This series documents the scientific basis for the evaluation of aquatic resources and ecosystems in Canada. As such, it addresses the issues of the day in the time frames required and the documents it contains are not intended as definitive statements on the subjects addressed but rather as progress reports on ongoing investigations.

La présente série documente les fondements scientifiques des évaluations des ressources et des écosystèmes aquatiques du Canada. Elle traite des problèmes courants selon les échéanciers dictés. Les documents qu'elle contient ne doivent pas être considérés comme des énoncés définitifs sur les sujets traités, mais plutôt comme des rapports d'étape sur les études en cours.

Research documents are produced in the official language in which they are provided to the Secretariat.

Morin, R. 2012. Estimating the age composition of discards in the NAFO 4T American plaice fishery. DFO Can. Sci. Advis. Sec. Res. Doc. 2012/081. ii + 29 p.

#### Abstract

Discarding of American plaice by the mobile gear fleet in NAFO Division 4T was widespread until appropriate management measures came into effect in 1994. To assess the status of the resource, it is necessary to develop a commercial catch at age that incorporates both the landed and discarded catches. This study was undertaken to estimate the size and age composition of American plaice discarded by mobile gear from 1976 to 2009. The method used to estimate discards combined length frequencies from landed catches with research survey length frequencies and retention ogives for the dominant mesh size used in the fishery. The approach was modified to take into account the distribution of the fishing fleet and the potential effect of unspecified flounder catches in the 1970s. Annual estimates of discards, as a percentage of the number of plaice caught, averaged $76 \%$ from 1976 to 1993 assuming a uniform distribution of catches within 4T, 12\% after 1993. The estimated rate of discarding was comparable to at-sea observer estimates for 1976, but less than observed discarding in three of four other comparisons from 1984 and 1990-1992. On the basis of minimum mesh sizes imposed since 1993, discarding should be minimal and may be overestimated in this study. However, estimates for the 1976-1993 period may be less than what occurred in the fishery.

## RÉSUMÉ

La remise à l'eau de plies canadiennes par la flotte d'engins de pêche mobiles de la division 4T de l'OPANO était très répandue avant l'entrée en vigueur de mesures de gestion adéquates en 1994. Pour évaluer l'état de la ressource, il est nécessaire de mettre au point un modèle de prises commerciales par âge, qui tient compte à la fois des prises débarquées et des prises remises à l'eau. La présente étude a été entreprise pour estimer la composition selon l'âge et la taille des plies canadiennes remises à l'eau par des engins mobiles entre 1976 et 2009. La méthode utilisée pour estimer les remises à l'eau associait les fréquences de longueur des prises débarquées aux fréquences de longueur des relevés de recherche ainsi que des courbes de rétention correspondant au maillage dominant utilisé dans le cadre de cette pêche. La méthode a été modifiée pour tenir compte de la distribution de la flotte de pêche et des effets possibles des prises de plies non précisées dans les années 1970. Les estimations annuelles des remises à l'eau, en tant que pourcentage du nombre de plies canadiennes prises, étaient en moyenne de $76 \%$ de 1976 à 1993, si on suppose que la distribution des prises était uniforme dans la division 4 T , et de $12 \%$ après 1993. Le taux estimé de remise à l'eau était comparable aux estimations réalisées par des observateurs en mer en 1976, mais inférieur aux remises à l'eau observées dans trois des quatre autres comparaisons pour 1984 et 1990-1992. En se fondant sur les maillages minimaux imposés depuis 1993, la remise à l'eau devrait être minime et pourrait être surestimée par la présente étude. Ainsi, les estimations pour la période de 1976 à 1993 pourraient être inférieures à la réalité de la pêche.

## INTRODUCTION

The number of fish caught and landed in a commercial fishery, in addition to their size and age composition, form the basis of analyses required to manage fisheries. When fish caught are discarded at sea, usually because they are smaller than the marketable size, landed catches no longer reflect total removals and uncertainty results for the management of the resource.

American plaice in NAFO Division 4T (Fig. 1) could be regarded as an example of how discarding can impact what we know of a fishery, from landings to the scientific advice required to manage the fishery. The at-sea discarding of plaice in the 4T trawl fishery first drew attention in the late 1950s, but despite increases in mesh size, there was little improvement in the level of discarding by the 1970s and 1980s. An annual quota of 10,000 tonnes was imposed in 1977 on 4T plaice and remained at that level until 1992, even as stock biomass declined in the 1980s. Stock assessments during that period noted that any reduction to the quota would only incite more discarding in the fishery (Tallman and Forest-Gallant 1990). Uncertainty in the catch-atage due to discarding made it impossible to successfully model population trends by conventional methods, such as sequential population analysis (Morin et al. 2001), further affecting the advice required for management of the resource.

In 1993, the 4T Atlantic cod fishery was closed to commercial fishing and a new era of fisheries regulations came into effect. Several management measures were applied to the 4T plaice fishery after 1993: reduced quota, mandatory landing of all fish caught, increased mesh size, minimum fish size regulations, increased observer coverage, dockside monitoring and by-catch limits on cod and other groundfish. These measures are reviewed in the following section.

In the late 1980s, technical reviews of the 4T plaice stock assessment recommended an approach to estimate the size and age composition of discards in the absence of extensive and annual observations of discarding at sea. Tallman (1991) presented a method that estimated discards by combining the observed size composition of commercial landed plaice with the research surveys of plaice that had been "fished" by retention ogives for mesh sizes used in the commercial fishery. This report updates estimates of discarding using the method presented by Tallman (1991) and presents a revised catch-at-age for the commercial fishery since 1976.

## NAFO 4T AMERICAN PLAICE FISHERY

Otter trawling was introduced to groundfish fisheries in the southern Gulf of St. Lawrence in 1947 (Jean 1963). The growth of trawling, followed by the introduction of Danish seining in 1958 (Powles 1969), resulted in rapidly increasing catches of American plaice. By 1965, plaice landings in 4T, not including discards, were over 10,000 tonnes (Morin et al. 2008), with trawls and seines accounting for over $90 \%$ of landed catches since then.

Table 2 shows the reported landings by the main gear types since 1976, the year that the DFO began systematic sampling of the size and age composition of landed catches of 4T plaice. Until the early 1980s, some landings in 4T were specified as "unidentified flounder". Powles (1969) estimated plaice landings, taking into account the expected species composition based on survey data. He reported that survey catches in the northern Magdalen Shallows were composed of $90 \%$ plaice and about $80 \%$ plaice in the southern half. The International Commission on North Atlantic Fisheries (the precursor of NAFO) revised landing statistics for 1963-1972 to account for unspecified flounder (ICNAF 1974), without specifying how the corrections were made. For this report, plaice landings were augmented by $90 \%$ of unspecified flounder landings, as an upper limit to plaice landings. In this report, the catch-at-age is
estimated with and without unspecified flounders for 1976 to 1983, along with associated discards by mobile gear.

The first quota regulation for 4T plaice was imposed in 1977 at 10,000 tonnes. Until 1977, there were few measures taken to regulate the fishery. Beginning in 1947, trawlers adopted a $75-\mathrm{mm}$ (3-inch) codend mesh size, but by 1959 most had adopted 114 mm (Powles 1969). There is some uncertainty as to what mesh sizes were used in plaice fisheries during the 1970s and 1980s. Clay et al. (1984) reported that up to 1976, the minimum codend mesh size was between 105 and 114 mm , depending upon the type of twine. In 1977, the minimum mesh size became 120 mm for most materials, and in 1981, it became 130 mm . Chouinard and Metusals (1985) reported the same mesh sizes in use and Tallman (1991) assumed these mesh sizes for his estimates of plaice discarding. However, Halliday et al. (1989) considered that, between 1976 and 1979, seiners should have used a minimum codend mesh size of 110 mm and trawlers should have used a minimum of 130 mm .

As previously stated, the closure of the 4T cod fishery in 1993 provoked a number of management measures affecting the plaice fishery. The plaice quota dropped to 5,000 tonnes, partly due to concern that vessels previously targeting cod would redirect their effort to other groundfish stocks. By 1993, and in ensuing years, other measures were introduced that either directly prevented discarded, or indirectly, though increased surveillance, made it more difficult to discard fish at sea.

- Mandatory landing of all fish caught (i.e. discarding became a violation).
- Mesh size increases.
- Minimum fish size regulations resulting in area closures when the number of fish caught below the minimum size was more than $15 \%$ of the catch.
- Observer coverage on $25 \%$ of trips in the directed plaice fishery.
- Dockside monitoring of all catches with mandatory notification on leaving and returning to port.
- By-catch limits on cod and other species in the plaice-directed fishery.

Data on mesh sizes in the 4T fishery since 1987, based on available electronic files of the southern Gulf observer program, reflect how the fishing industry implemented the regulatory changes that occurred during the 1990s (Fig. 2). Vessels directing for plaice in 4T from 1987 to 1992 predominantly used $130-\mathrm{mm}$ diamond mesh. The same analysis (not shown) for 4T coddirected fishing also indicated that $130-\mathrm{mm}$ diamond mesh was the dominant mesh size from 1987 to 1992. In 1993, 130-mm square mesh was proposed for cod-directed fishing. The observer data indicate that the industry complied by shifting to 130 mm square mesh, with some vessels adopting larger mesh sizes. In 1994, $145-\mathrm{mm}$ square mesh was recommended, but many vessels continued to adopt larger meshes. By 1995, 152-mm mesh ( 6 inches) was required and, in 1996 until present, $155-\mathrm{mm}$ square mesh has been the minimum requirement for plaice-directed fishing in 4T. Throughout the 1990s, the fishing industry responded to changing mesh size regulations, either accepting that minimum or adopting larger mesh sizes (Fig. 2).

## DATA SOURCES

## OBSERVER DATA

Before 1994, when it became mandatory to land all plaice caught at sea, discarding was periodically assessed by deploying observers on fishing vessels. The Gulf Region Observer Program was introduced in 1981 to observe the domestic and French fleets in NAFO divisions 4RST and 3Pn, providing data and information required for stock assessment and management, but also monitoring the compliance of fleets with current regulations (Kulka and Waldron 1983). Observer data also contribute to the biological assessment of 4T plaice by augmenting the sampling that is made in landing ports (Morin et al. 2008).

Although biologists drew attention to discarding in the 4Tplaice fishery in the 1960s, it appears that observers were not thereafter deployed in any consistent manner. Table 1 summarizes the published estimates of the weight and the number of discarded plaice as a percentage of the total catch. All of these estimates were based on at-sea observed catches, sometimes combined with port sampling of either the same vessels or catches from vessels in the same fishing area. With the exception of the studies in 1976 and 1984 (Halliday et al. 1989, Chouinard and Metusals 1985, respectively), most of the estimates were made with relatively few fishing trips in restricted areas of the southern Gulf fishery.

Observer data in electronic files for the southern Gulf are currently available yearly since 1990. The data from 1984 used by Chouinard and Metusals (1985) were transcribed to electronic files for this study. Of the 10 trips that were reported from their study, our data files record nine; however, our estimates of discarding are similar to those in Chouinard and Metusals (1985). Discarding estimates were also compared with the results of at-sea observers in 1984 and 1990-1992. In the latter three years, observers recorded discarding by vessels directing for American plaice in 4T on six vessel trips in 1990, 13 trips in 1991 and 9 trips in 1992.

## PORT SAMPLING

Since 1976, commercial catches of plaice in 4T have been sampled at landing ports throughout the active months of fishing (Morin et al. 2008). The sample requirements consist of sexed length frequencies, with otoliths removed for age determination at a sampling rate of one per sex, per cm length. In all cases, the location of the capture and the weight of the catch are recorded and corrections are applied when the catch was graded by size or category. Lengthweight relationships established from annual research surveys are used to convert numbers-atlength of male and female plaice to estimates of the sample weight.

Separate age-length keys are determined for seines, trawls and fixed gears (mainly longlines and gillnets). Keys are further separated into two seasons, up to and after July 31, to account for growth changes. A description of the sampling up to 2007 may be found in Morin et al. (2008).

## RESEARCH SURVEYS

Groundfish stocks in 4T have been surveyed by experimental trawling every September since 1971 using a stratified random design (Hurlbut and Clay 1990). The survey area was initially divided into 24 strata, mainly on the basis of depth and fish distribution. In 1984, three inshore strata were added to the survey (Fig. 3), but these are at the margin of plaice habitat and are not used for analyses of plaice abundance and size distribution.

The survey provides a continuous time series of abundance and size and age composition of 4T plaice. Any changes to the trawl or the survey vessel have been accompanied by comparative fishing experiments wherein the old and the new gear or vessel were fished in parallel (Benoît 2006). An exception to this is the survey of 2003, when mechanical failure of the survey vessel resulted in a non-calibrated vessel being used. Time limitations also caused two strata to be missed and another two to be sampled with only one trawl set. As a result, the 2003 research survey has been dropped from the time series for all groundfish stocks.

Most sampling procedures in this survey have remained constant since 1971 (Hurlbut and Clay 1990). The length frequencies of plaice have been sex-based, with the exception of three years (1984-1986) when sexes were combined. Sampling for biological information, such as age and maturity, is conducted at a rate of one sample per sex, per cm length.

#### Abstract

ANALYSES Tallman (1991) presented a general approach to estimating the number of discarded fish at age in the 4T plaice fishery. This approach can be summarized in four steps:

1. Obtain the research survey population-at-length for $4 T$ plaice in a given year and the landed catch-at-length for mobile gears (trawls and seines) in the same year, based on port sampling and observer data.
2. Obtain published retention ogives for the required (or dominant) mesh size for each year of the fishery. These ogives estimate the proportion of plaice of any given length that is retained by that mesh size. Multiply the survey population-at-length by the appropriate retention ogive. This effectively "fishes" the survey population to generate a theoretical length frequency distribution of plaice (TLFD) for the fishery in a given year.
3. Scale the TLFD to the landed catch-at-length across lengths that are not discarded by the fishery. The difference between the scaled TLFD and the landed catch-at-length is the length distribution of discarded plaice in that year's fishery.
4. Convert the discarded length frequency to male and female length frequencies based on the research survey sex ratios at each length. Apply the annual research survey agelength key for each sex to estimate the age composition of discards.

At step 1, the research survey is assumed to provide an unbiased representation of the size and age structure of the $4 T$ plaice population. Clay (1979), cited by Tallman (1991), estimated that the $6-\mathrm{mm}$ codend mesh that was used in the survey trawl from 1971 to 1985 (increased to 19 mm in 1986) would retain $50 \%$ of plaice of 7 cm in length. In fact, the modal size of plaice has averaged 24.5 cm from 1971 to 2007 (range 18-28 cm), suggesting that plaice may not become fully recruited to the survey trawl gear, possibly by about 25 cm . Any under-representation of plaice in the survey at sizes of 22 to 25 cm would potentially under-estimate discarding, particularly at mesh sizes of 110 and 120 mm . At those sizes, a $110-\mathrm{mm}$ mesh retains between $9 \%$ of plaice of 22 cm and $43 \%$ of plaice at 25 cm ; at 120 mm , plaice are retained at 3 and $17 \%$ for corresponding sizes.

Retention ogives for 110 and $120-\mathrm{mm}$ meshes were taken from Clay et al. (1984). The selectivity of four meshes for American plaice was studied for Scottish seiners in the southern Gulf in 1993 (Tait 1993). That study was the origin of retention ogives for $130-\mathrm{mm}$ square and diamond meshes and the study of Walsh et al. (1992) for $155-\mathrm{mm}$ square mesh. Codend mesh sizes were assumed to be 110 mm in 1976, then 120 mm from 1977 to 1980 and 130 mm diamond from 1981 to 1992, as described by Clay et al. (1984 ), Chouinard and Metusals (1985) and used by Tallman (1991). However, discarding was also estimated using the gear-specific
codend meshes suggested by Halliday et al. (1989) from 1976 to 1979: 110 mm for seines and 130 mm for trawls. The dominant mesh size for the 1993 directed plaice fishery was $130-\mathrm{mm}$ diamond (Figure 2), as required in the management plan for that year. I assumed a codend mesh size of $155-\mathrm{mm}$ square since 1994.

For each mesh size, the proportion of plaice retained at each length, $r(l)$, was modelled with a logit function:
$r(l)=\frac{\exp \left(k\left(l-l_{0.5}\right) / s_{r}\right)}{1+\exp \left(k\left(l-l_{0.5}\right) / s_{r}\right)}$
where $k$ is the constant $2 * \ln (3)=2.197, I_{0.5}$ is the length at which $50 \%$ of plaice are retained, $s_{r}=$ $I_{0.75}-I_{0.25}$ (the difference between the length at which $75 \%$ and $25 \%$ of plaice are retained). The theoretical length frequency distribution of the fishery (TLFD) in a given year was obtained by multiplying the research survey population-at-length by $r(l)$ for the appropriate dominant codend mesh size for the fishery in the same year.

The third step in the analysis involved rescaling the TLFD to be equivalent to the observed landed catch-at-age for the fishery in the same year. Tallman (1991) proposed to do this by multiplying the TLFD by the ratio of the sum of theoretical and observed catches across a range of non-discarded lengths. He proposed a lower limit of 40 cm for non-discarded plaice and an upper limit of 60 cm , beyond which sampling may be sporadic. Powles (1960), Chouinard and Metusals (1985), and Halliday et al. (1989) all reported that plaice were discarded mainly up to 35 cm in length. However, some authors (Cliche and Côté 1984 and Chouinard and Metusals 1985) also observed significant levels of discarding at lengths between 35 and 40 cm . The same range of sizes as Tallman ( $40-60 \mathrm{~cm}$ ) on which to adjust the TLFD was chosen for the period up to 1993. Adjusting the TLFD on plaice lengths between 35 and 60 cm effectively reduced the overall level of discarding estimated, usually by within $5 \%$.

Fishery regulations were imposed in 1994 that set limits on the number of plaice of 30 cm and less that are caught in the 4T fishery. With dockside monitors verifying the size distribution of each catch, it seemed reasonable to assume that any discarding after 1993 would have occurred at no more than 30 cm in length. However, the size range of non-discarded plaice was restricted to 32 to 60 cm for the period 1994-2009. Moving the lower limit for adjusting the TLFD from 30 to 32 cm also tended to increase the estimates of discarding by less than $3 \%$.

In addition to scaling the TLFD to the landed catch-at-length, an alternative approach of regressing the landed catch-at-length against the theoretical number of non-discarded fish was used. The slope of this relationship, with no intercept, provided similar estimates to the catch ratio method proposed by Tallman (1991). The slope of the regression of catches indicated how well the two length distributions (theoretical and observed catch-at-length) correspond over nondiscarded lengths. The regression method also made it possible to test the assumption that the theoretical catch is related to the observed catch as a linear function, independent of fish length (an assumption that would be implicit in using the ratio of the two variables to scale the TLFD). By resampling with replacement the regression of the observed catch-at-length on the TLFD, confidence limits were determined for the estimates of discarded plaice.

The length composition of discarded plaice was estimated by subtracting the observed landed catch-at-length from the scaled TLFD. Negative values were set to zero and an upper size limit for discarded plaice was set at 40 cm , beyond which any (always small numbers) of discarded plaice were also set to zero.

Up to this point, discarding was estimated on the total catch of plaice, sexes combined. The sex composition of discarded plaice was then estimated by the ratio of female: male at each cm in the research survey data. The sex ratios in the 1984 to 1986 surveys, when plaice length frequencies were not sexed, were estimated by a local regression model (loess) with year and length factors. The model was based on the proportion of females observed five years before and five years after the 1984-1986 period. Predicted values of the female proportion were generated over the three years (1984-1986) and lengths of 10 to 68 cm .

The age composition of discarded plaice was determined by applying the annual age-length keys for male and female plaice obtained from the research surveys to the length composition of discards.

## SPATIAL EFFECTS

Tallman (1991) noted that the fleet exploiting American plaice does not fish throughout 4T with uniform intensity. The TLFD estimated in the manner described above assumes, on the contrary, that the fishery is conducted uniformly throughout 4T or that there are minor local differences in the size composition of plaice. He proposed a modification that takes into account the spatial distribution of fishing by NAFO unit area (Figure 1).

The method involves, first, taking the research survey population-at-length in each stratum and converting this to the population-at-length in each unit area. Knowing the coordinates of the boundaries of each stratum $i$ and each unit area $j$, it is possible to calculate the proportion of the area of a stratum that contains any given unit area, $\mathrm{P}_{i j}$. The population at each length in unit area $j$ that is within stratum $i$ is obtained by multiplying $P_{i j}$ by the research survey population $\left(N_{i}\right)$ in stratum $i$. The total population in unit area $j\left(N_{j}\right)$ can then be obtained by summing across all strata.

$$
N_{j}=\sum_{i}\left(N_{i} \cdot P_{i j}\right)
$$

The theoretical length frequency distribution, corrected for fishing activity, is then calculated by weighting $\mathrm{N}_{j}$ by the landings that occurred in unit area $j$ :
$\sum_{j}\left(N_{j} \cdot Q_{j}\right)$
where $\mathrm{Q}_{\mathrm{j}}$ is the proportion of annual landings occurring in unit area $j$.
The decision of whether or not to correct the TLFD for fishing activity depends on a number of factors. The research survey is conducted every September when plaice are dispersed throughout the southern Gulf, before they move into channel waters to overwinter. If 4T plaice were segregated geographically by size, age or sex during the survey, the distribution of the fishery would be expected to influence estimates of discarding by the method proposed in this study. This would be a reason for applying a spatial correction to the TLFD. However, if the 4T fishery was conducted at times of the year when plaice are not dispersed (e.g. in early spring during movement into the Gulf and spawning, or in late fall when plaice move offshore), the size composition of plaice in the research survey would be unrelated to the population exploited by the fishery during these periods. The proposed spatial correction to the TLFD would not be able to resolve this effect. The approach adopted for this study was to estimate discards by comparing the results with and without correcting the TLFD by the spatial effect of fishing activity.

## RESULTS

Unidentified flounder catches in 4T that could be assigned to American plaice contributed up to $12 \%$ of the recorded landed catch between 1976 and 1983 (Table 2). In that period, gillnets or unspecified gear contributed most of the unidentified flounder that were considered to be plaice. For mobile gear, from which discarding was estimated, unidentified flounder increased the reported plaice landings by, at most, 3\%. The commercial catch-at-age (Table 3) was also revised for the 1976-1983 period to include plaice reported as unspecified flounder (Table 4). The increase in the numbers of landed plaice reflect the change in the weight of the landed catches, ranging from 4 to $13 \%$, with the exception of 1981 when unspecified flounder catches would have increased the reported landings by only $1 \%$.

Across lengths of plaice that were assumed not to be discarded (40-60 cm before 1994; 32-60 $\mathrm{cm}, 1994 \mathrm{on}$ ), the regressions of the observed length frequency on the theoretical catch-atlength were highly significant, with coefficients of determination $\left(R^{2}\right)$ exceeding 0.85 in most years (Table 5). The exception was the 2008 fishery, for which there was no significant relationship between the estimated and observed abundance at lengths assumed not to be discarded. Despite the high level of $\mathrm{R}^{2}$ in Table 5, a closer examination of the relationship between the theoretical and observed catches at each length revealed that after 1993, the relationship was distinctly curved (Figure 4). Since Figure 4 pairs commercial and theoretical catches at each fish length, with highest catches at the smallest lengths, a linear regression on data after 1993 will tend to estimate a higher commercial catch than observed at small sizes. The estimation of discarding used an adjustment of the TLFD based on a linear relationship between theoretical and observed catches at 32-60 cm after 1993. However, the lack of a linear relation across all non-discarded lengths will result in some degree of overestimation of discarding of small fish.

Discarding estimated using the model that takes into account the distribution of the plaice fishery by unit area (the area effect) varied more widely from year to year than the model without the area effect (Table 5). From 1976 to 1993, discarding averaged 58\% annually with the area effect model, with a coefficient of variation (CV) of $26 \%$. Without the area correction, discarding averaged $76 \%$ annually over the same period, with a CV of 12\%. From 1994 to 2009, the two models produced very similar estimates of discarding, averaging $12 \%$ and with CV's of 52 to $53 \%$. The estimates of discarding by the area-effect model produced anomalous results for 1984 and 1986 (discarding <30\% by number, Table 5). This result for 1984 is well below the estimate obtained by observed catches in 4TkIng in the same year ( $61 \%$, Table 1).

Much of the discrepancy between the two modeling approaches can be accounted for by uncertainties in the landings by NAFO unit area until the 1990s. Logbooks only became a condition for licensed fishing of groundfish in the southern Gulf in 1991. Between 1976 and 1990, there were 11 years when over $20 \%$ of annual plaice landings were made without a record of the unit area in which the catch was made (labelled "unknown" in Figure 5). In the early 1990s, the plaice fishery became increasingly concentrated in the eastern half of 4T, unit areas 4 Tfg , as opposed to areas 4 Tklmn in the western part of 4T (Figure 5). However, given the high proportion of landings before 1991 that could not be attributed to any unit area, it is unreasonable to apply the area correction to discard estimates. From 1991 onwards, the two methods of estimating discarding produced similar results, differing by less than $2 \%$ in most years (Table 5, Figure 6). Up to 1990, discarding estimates based on the correction due to fishing area led to variable and, at times, unreliable estimates of discarding. I proceeded with estimates of discarding with a model that does not adjust the estimated population numbers-atlength by the catch levels in unit areas up to 1990 and a model that makes this adjustment from 1991 onwards.

Discarding estimates were also made using the mesh sizes that Halliday et al. (1989) considered to be possibly in use from 1976 to 1979. Table 6 shows the estimates of discarding, assuming that 110-mm codends were used by seines and 130 mm used by trawls during those years. The model used for these estimates assumed no area effect, therefore similar to the last column in Table 5. Discarding rates dropped using this choice of mesh sizes and were considerably less than the discarding rate reported by observers to be 74\% Halliday et al. (1989). A similar estimate of discarding was obtained for seines in 1976 (68.5\% vs 66\% by Halliday et al. 1989), but less than observed discarding by trawlers (48.5\% vs 76\% by Halliday et al. 1989). I concluded that the $130-\mathrm{mm}$ codend mesh size suggested by Halliday et al. for trawlers was inconsistent with the mesh size reported by other authors to be 110 mm and led to an underestimation of discarding.

Figure 7 shows the adjusted theoretical length frequency distribution for 1976. The area between the two curves, from 10 to 40 cm represents the estimated discards. Halliday et al. (1989) reported that discarding occurred mainly between 20 and 35 cm , with a mode at 28 cm . Similar results are shown for the estimated length composition of discards in 1976, which also obtained a mode at 28 cm (Figure 7). Similar length frequencies, observed and estimated, with the length composition of estimated discards are also shown in Figure 7 for analyses of 1999 and 2006 data. These two years were displayed because they are typical of the pattern observed in estimates made for years since 1993. In this period, the descending portion of the estimated length frequencies is not as well fitted to the observed catch-at-length in the mobile gear fisheries. Given the large mesh sizes that has been used in the fisheries after 1993 (145 and $155-\mathrm{mm}$ meshes), the size range of discards has declined, along with the capture of plaice less than 25 cm .

Comparisons were made of estimated discarding with observations made at sea in the same year. The 1984 data analyzed by Chouinard and Metuzals (1985) indicated a higher rate of discarding in the smaller size range of plaice than estimated in this study, particularly below 30 cm (Figure 8A). Chouinard and Metuzals (1985) reported 61\% discarding by number; the estimate provided here is $42.6 \%$. Results were similar in comparisons with observer data from 1990 and1992, with a tendency to both underestimate below 30 cm and overestimate above 35 cm (Figure 8). The comparison for 1991 was unusual both for the observed discarding (low level of discarding observed at $<30 \mathrm{~cm}$ ) and for the estimated discards which overestimated both small and large plaice (Figure 8C, 1991).

The discarded catch-at-age, combining male and female plaice, is presented in Table 7. The discarded catch-at-age dropped sharply in 1994 with the regulatory increase in codend mesh size and declines in landed catches that began in 1993. The modal age of discarding ranged between 6 and 10 years of age, but most frequently 7 or 8 years-of-age from 1976-1993 and 8 or 9 years-of-age from 1994-2009. Estimates of the discarded catch-at-age were also made for trawl and seine catches that would have been identified as unspecified flounder from 1976 to 1983 (lower section of Table 8). Although the landed catch-at-age increased considerably for some years during this period (upper section of Table 8), most of the unspecified flounder were associated with fixed gear. Discards associated with unspecified flounder increased the previously reported landings of plaice by less than 3\%.

Table 9 presents the geometric means of discarded plaice at age resulting from 5,000 bootstrap iterations of the linear regressions used to adjust the TLFD to the observed catch-at-length. Over most ages and years, the bootstrap estimates of mean discarding closely followed the initial estimates presented in Table 7. However, Table 10 shows the increase in uncertainty associated with estimates of discarding after 1993, with CV's by more than tenfold (shown graphically for age-10 plaice in Figure 9).

## DISCUSSION

In retrospect, it appears that more could have been done to quantify discarding with at-sea observers, particularly when it was known to occur at such a high frequency and level. The early studies of plaice discarding served to identify a serious problem in the mobile gear fisheries; however, they failed to provide a comprehensive estimate of discarding at the level of the 4T fishery. Even the most extensive study documented by Halliday et al. (1989) was based on 47 vessel trips, a fairly modest deployment compared to recent observer programs that assign observers to $25 \%$ of vessel trips. In contrast, data on the 1991 and 1992 fisheries (just before discarding regulations came into effect) indicate that over 600 trips were made each year by boats directing for plaice in 4T with mobile gear.

The current observer program in NAFO 4T is not without problems, however. Benoît and Allard (2009) demonstrated that observers are not deployed randomly across all active vessels and that the catch composition of vessels changed in the presence of an observer, suggesting that normal fishing practices are not represented by observed vessels. It is not possible to assert whether the same problems applied to the 4T plaice fishery before 1994. Prior to that year, discarding was permitted and vessels were only required to adopt the minimum mesh size in effect. However, it cannot be assumed that fish harvesters were indifferent to the level of discarding recorded by observers and it may be possible that there was some tendency to minimize discarding in the presence of an observer.

The method applied in this study, based on Tallman (1991) estimates discarding independently of observers. Tallman's method, similar to those of Mayo et al. (1981) and Casey (1996), assumes that a relationship exists between the survey-based length composition of a fish population, adjusted for the mesh size of commercial gear, and the discarding of a commercial fleet exploiting the same population. I have shown that over 24 years in the 4T plaice fishery, with few exceptions, a significant relationship may be found for non-discarded lengths. However, this relationship was questionable for the period since 1994 and it may have resulted in an overestimation of recent discarding of plaice.

Although not the basis for these estimates, empirical observations at sea are required to validate the method. In the period when discarding was widespread, observer deployment was minimal; since 1994, any vessel inclined to discard plaice in 4T would not do so in the presence of an observer without risking a violation. The estimate of discarding in 1976 compare favourably (although only qualitatively) with the results of Halliday et al (1989). Compared to observer studies in the 1980s and early 1990s, my results tended to underestimate discarding at less than 30 cm and possibly overestimate at larger size of $35-40 \mathrm{~cm}$.

One of the limitations of the method used in this study is that it estimates discarding solely on the basis of the expected catch due to the mesh size in use at the time of the fishery. The method also relies on the population size structure that is provided by the research surveys which, in turn, may not be fully selective for plaice at small sizes. Partly for these reasons, the results presented here, particularly for smaller plaice ( $<30 \mathrm{~cm}$ ) should be regarded as minimum estimates. Mesh size is obviously critical to the size composition of plaice catches; however, it can only account for a portion of discarding. Discarding was also a human activity, practiced with methods and motivated for reasons that may never be fully known.

## ACKNOWLEDGEMENTS

Ross Tallman made the work possible by introducing this method of estimating plaice discards. Doug Swain and Francois Aucouin contributed through discussions on this subject. Tobie Surette provided area estimates for survey strata and management areas in 4 T . I also thank Sophie Leblanc and Claude LeBlanc for their editorial comments on this manuscript.

Table 5. Estimates of the percentage of mobile gear catches of 4T American plaice fishery discarded at sea, according to two models. The "area effect model" weights the survey population length distribution of plaice annually in each NAFO unit area by the level of fishing. The alternative model assumes that the fishery is distributed evenly throughout NAFO $4 T$. RSQ refers to the $R^{2}$ of the regressions used to adjust the observed and estimated abundance at non-discarded lengths, required to estimate discards (see text). No estimate was made for 2008 due to non significant regression models.

Table 6. Estimates of discarding rates assuming mesh sizes suggested by Halliday et al. (1989), i.e. seines using 110 mm codend mesh size; trawls using 130 mm . Estimates were made using a model that does not weight population length composition by unit area landings (comparable to last column in Table 5).

| Year | \% <br> discard |

Table 10. Coefficients of variation (\%) of bootstrap estimates of discarded catch-at-age of American plaice. Discard estimates were made in units of 1000 plaice. Negative values of the cv are associated with mean discard estimates of less than 1000 plaice. Extreme values of the c.v. are denoted by symbols: * signifies less than -100\%; + signifies greater than 100\%.

Figure 1. The southern Gulf of St. Lawrence showing the unit area designations of NAFO 4T.

Figure 2. Codend mesh sizes used by mobile gear (seines and trawls) in NAFO 4T, 1987 to 2009. Mesh sizes were averaged by individual vessel trip before being counted by year or group of years. Changes to the regulations on minimum mesh size were made in 1993, 1994 and 1995 (see text).

Figure 3. Southern Gulf of St. Lawrence (NAFO Division 4T) showing stratum boundaries in the annual trawl survey.

Figure 4. Plots of commercial catch-at-length, observed and estimated from survey data and mesh selectivity (theoretical), for selected years. Linear regressions were fitted to the 1976 and 1985 data and quadratic regression models were fitted to the 1994 and 1998 data.

Figure 5. The proportion of landed catches found in the main fishing areas of NAFO 4T: in unit areas of eastern $4 T$ (4Tfg) and in western $4 T$ (4TkImn). Until 1990, some landings were made without reporting the unit area from which they were made (unk).

Figure 6. Total rates of estimated discarding based on a model that takes into account the spatial effect of fishing activity (area effects) and a model that does not take into account area effects due to fishing activity.

Figure 7. Left graphs: length frequencies of landed catches of $4 T$ plaice in selected years (blue line) and the theoretical catch (red line; see text). The graphs at right show the estimated length composition of discards, i.e. the positive difference between the theoretical catch and the observed landed catch.

Figure 8. Upper left graph shows the observed discards (broken line) and retained catch (solid line), estimated by Chouinard and Metuzals (1985). Upper right graph shows estimated discards (broken line) and commercial catch (solid line) from port sampling of plaice catches in 1984. Remaining graphs compare logistic regressions from observed and estimated rates of discarding in the 1984 and 1990-1992 fisheries.

Figure 9. Coefficients of variation on age-10 plaice resulting from 5,000 bootstrap estimates of discarding. No estimates were made for 2003 and 2008.
