E1C 9B6

This series documents the scientific basis for the evaluation of aquatic resources and ecosystems in Canada. As such, it addresses the issues of the day in the time frames required and the documents it contains are not intended as definitive statements on the subjects addressed but rather as progress reports on ongoing investigations.

Research documents are produced in the official language in which they are provided to the Secretariat.

This document is available on the Internet at Ce document est disponible sur l'Internet à www.dfo-mpo.gc.ca/csas-SCCs

La présente série documente les fondements scientifiques des évaluations des ressources et des écosystèmes aquatiques du Canada. Elle traite des problèmes courants selon les échéanciers dictés. Les documents qu'elle contient ne doivent pas être considérés comme des énoncés définitifs sur les sujets traités, mais plutôt comme des rapports d'étape sur les études en cours.

Les documents de recherche sont publiés dans la langue officielle utilisée dans le manuscrit envoyé au Secrétariat.

Chaput, G., and Douglas, S. 2012. Estimated returns of Atlantic salmon (Salmo salar) to the Miramichi River and each branch, 1998 to 2011. DFO Can. Sci. Advis. Sec. Res. Doc. 2012/102. ii + 56 p.

#### Abstract

A hierarchical Bayesian mark and recapture model is used to estimate returns of Atlantic salmon (Salmo salar) adults by size group to the Miramichi River and to each branch for 1998 to 2011. The model uses auxiliary data from counts of salmon at three headwater barrier fences to estimate returns annually for the early-run (prior to August 1) and for the whole year. Model fit is assessed by examining observed to predicted recaptures at three estuary trapnet locations. Retrospective analysis is used to assess the stability of previous years' estimates of returns as recent years observations are added to the model. Estimated returns using the hierarchical model are less uncertain and differ in some years from independent annual assessments. Future modifications to the model include incorporating angling catch and effort data and extending the model back to 1984 when mark and recapture programs were less intensive and for which angling data and barrier count information could be used to advantage to estimate the return of Atlantic salmon to the Miramichi River.

## RÉSUMÉ

Un modèle bayésien hiéarchique de marquage et de recapture est utilisé pour évaluer les montaisons de saumon atlantique (Salmo salar) par groupe de taille à la rivière Miramichi et pour les deux affluents principaux pour les années 1998 à 2011. Ce modèle utilise des indicateurs auxiliaires d'abondances provenant de décomptes à des barrières en rivière pour évaluer les montaisons d'été (avant le $1^{\mathrm{e}}$ août) et pour toute l'année. L'ajustement du modèle est vérifié en comparaison des observations et des valeurs prédites de recaptures aux trois filets-trappes dans l'estuaire. Une analyse rétrospective est présentée pour évaluer la stabilité des estimations annuelles antérieures lorsqu'on ajoute de nouvelles années d'observations. Les estimations de montaisons provenant du modèle hiéarchique sont plus précises et, pour certaines années, diffèrent de celles obtenues avec un modèle annuel non-hiéarchique. Des modifications futures à considérer incluent l'utilisation des indices de captures et des efforts de la pêche récréative ainsi que l'évaluation des montaisons antérieures commençant en 1984. Pour ce dernier travail, le programme de marquage et de recapture était moins élaboré et dans ce cas les indices d'abondance provenant de la pêche récréative et des barrières de dénombrement pourraient être utilisés davantage pour estimer les montaisons du saumon atlantique à la rivière Miramichi.

## INTRODUCTION

The Miramichi River, located in central New Brunswick, has a maximum axial length of 250 km and drains an area of about $14,100 \mathrm{~km}^{2}$. There are two major branches: the Northwest Branch covers about $3,950 \mathrm{~km}^{2}$ and the Southwest Branch about $7,700 \mathrm{~km}^{2}$ of drainage area (Bousfield 1955). The two branches drain into a common estuary and subsequently drain into the Gulf of St. Lawrence at latitude $47^{\circ} \mathrm{N}$ (Fig. 1).

The Miramichi River is considered to contain several stocks of Atlantic salmon (Saunders 1981). Separate branch assessments were introduced in 1992 to account for some of this diversity and for the differences in exploitation between the Northwest and Southwest branches. Aboriginal fisheries were historically conducted almost exclusively in the Northwest Miramichi (exploitation also occurs in the estuarial waters of the Miramichi River, downstream of the confluence of the two branches) and recreational fisheries exploitation also differs between the Northwest and Southwest branches.

Temporal stock distinctiveness has been highlighted as an important component of the Atlantic salmon resource (Saunders 1967). Early runs (prior to Aug. 1 in this paper; up to Aug. 31 in previous assessments) and late runs have different composition in terms of small and large salmon proportions. The early runs in both branches are also exploited more heavily than the late runs (Randall et al. 1990).

For fisheries management purposes, two size groups of salmon are defined. The small salmon category consists of fish less than 63 cm fork length and are generally referred to as grilse. These fish have usually spent only one full year at sea (one-sea-winter) prior to returning to the river but the size group may also contain some previously spawned salmon. The large salmon category consists of fish greater than or equal to 63 cm fork length. This size group is generally referred to as multi-sea-winter or just salmon and contains varying proportions of one-seawinter, two-sea-winter and three-sea-winter maiden (first time) spawners as well as previous spawners (Moore et al. 1995).

In the context of the Miramichi, estimates of returns to each branch are desired. It is not possible to obtain absolute counts of salmon in the Miramichi due to its physical size. As a result, the use of partial capture techniques to sample the runs necessitates the use of mark and recapture models to estimate run sizes.

Since 1992, assessments of the returns of salmon to the Northwest and Southwest branches have been prepared. Returns by size group to the whole river were partitioned into Northwest and Southwest Miramichi returns. The most recent assessment is available in DFO (2010) and Chaput (2010).

## MATERIALS AND METHODS

## TRAPNETS

The trapnets used in the Miramichi are for the most part T-trap designs as used in the historical commercial salmon fishery and in the commercial gaspereau fishery. V-trap designs were used at the Northwest recaptured traps in some years. The T-trap designs evolved to include a backchannel linking the upper and lower traps in the late 1990s. Trapnet specific details are provided in Hayward (2001) and Chaput (2010).

The returns of salmon to the Miramichi can extend from the middle of May to early November. Since 1994, facility M26 (Millerton) is considered the DFO science index facility for the Southwest Miramichi whereas in the Northwest Miramichi, facility M05 (Cassilis) has become the DFO science index trapnet since 1998 (Fig. 2).

## Processing of Catches at the trapnets

All fish captured at the trapnets were enumerated by species. Atlantic salmon were captured with a dipnet, placed in sampling boxes in water and measured for fork length (to the nearest $0.1 \mathrm{~cm})$. Sex determination was made based on external characteristics and is considered unreliable prior to August. Wild fish were distinguished from hatchery origin fish on the basis of the presence of the adipose fin, this fin having been removed prior to stocking on the majority of hatchery produced juvenile salmon. Scale samples, for determination of age, were removed from the standard location (along the imaginary line joining the posterior of the dorsal fin and the anterior of the anal fin, two to four rows above the lateral line) from all large salmon and from varying proportions of small salmon. Scale samples were stored dry.

Prior to release, Atlantic salmon were marked with individually numbered blue Carlin tags (dimensions 9.5 mm by 4.6 mm by 1.0 mm thick) attached to the back just anterior to the dorsal fin with narrow gauge stainless steel wire. In most years, some salmon were released back to the river untagged because of injuries, to reduce stress during warm water events, or as a result of a catch in excess of the daily allotment of tags to be placed on small salmon. In those cases, the caudal fin was hole punched prior to releasing the fish, with upper or lower caudal punch specific to the branch. Caudal punching of the tail was restricted to the Northwest Cassilis trapnet (M05) and the Southwest Millerton trapnet (M26).

All salmon captured in trapnets (both at monitoring facilities and in the food fishery) were examined for the presence of a Carlin tag. In the case of Carlin tagged fish, the tag number, the size (small or large based on length), date and trapnet location where captured were recorded. Caudal punched fish and associated information were also noted before release at the index trapnets.

Food fishery catches at Eel Ground (M23 and M39 in Fig. 2) and Red Bank (M09 and M31 in Fig. 2) were sampled for number of salmon caught (by size) and number as well as sex of salmon harvested (by internal examination). Fish were examined for Carlin tags and when present the number was recorded prior to release or at sampling.

## Treatment of Data

All the data were entered in spreadsheets and a coding hierarchy was derived for categorizing the fish sampled from the trapnets (Chaput 2010). Summaries by facility, size group and month of the catch, tagging and recapture histories were developed to construct the marking and recapture data series.

## Barrier fence monitoring

There are three headwater protection barriers in the Miramichi, two in the Southwest Miramichi River (Dungarvon, Juniper) and one in the Northwest Miramichi River (Northwest Miramichi) (Fig. 1) (Madden et al. 1999). The two Southwest Miramichi barriers began operations in 1981 and the Northwest Miramichi began operation in 1988. Salmon are counted and contained into a
holding pool where they are held and released to continue migrations upstream in late fall. Counts of salmon are obtained by small salmon and large salmon categories (Table 1).

## Mark and recapture models

The estimation of the returns to the Miramichi is complicated by several factors including movement of tagged fish between branches and potentially different capture probabilities by trapnet. Returns to the branches are based on returns at the recapture locations. It was assumed that there was $10 \%$ mortality from tagging and handling (Chaput et al. 2000). Annual and hierarchical Bayesian models (Appendix 1) are used to estimate the returns of salmon by size group, to the Miramichi and to the Southwest and Northwest Miramichi branches separately (Chaput 2010).

Following on recommendations from a previous review in March 2010 (Chaput 2010; DFO 2010), the counts of fish at the headwater barriers in the Northwest Miramichi (NWMiramichi) and at the Dungarvon River barrier of the Southwest Miramichi (SWDungarvon) were considered as indices of the early run components of each branch (early run is prior to August 1). The counts at the Juniper barrier in the Southwest Miramichi are considered to be an index of total run to the Southwest Miramichi. In addition, the data for 2010 and 2011 for the Juniper barrier are considered incomplete due to the intermittent monitoring operations and these years were excluded from the version of the model used in 2011.

## Data for 1998 to 2011

The 1998 to 2011 mark and recapture data were verified, and corrected (Tables 2 and 3).

## Changes from most recent assessment (Chaput 2010)

Salmon sampled at trapnets subsequently move between branches. In previous years, all fish captured and released from the two index trapnets were marked before release in order to identify their state of capture, first time catch or previously caught. This was done to address the issue of repeated catches at the trapnets. The estimates of returns to each branch and overall were based on the first time catch only. Carlin tagged fish were treated in the same way, first time recaptures were treated as valid recaptures if the tagged fish originated from another tagging trapnet. However, multiple recaptures of such fish, as for example, a salmon tagged in the NW Miramichi at Cassilis and seen again a second or more time at the SW Miramichi trapnet at Millerton were excluded from the recapture data vector.

In 2011 and in a few other years, warm water events necessitated the release of fish from the trapnet without marking. Some of these unmarked fish released from the trapnet could have been captured again although it would not be possible to know. In addition, tail punching ceased in 2011 to reduce stress on fish, previous experience indicated that in some cases, caudal punches resulted in excessive fraying and damage to the caudal fin. For 2011, multiple recaptures of Carlin tagged fish were included in the recapture categories as multiple catches of unmarked fish could not be excluded.

The models now estimate the abundance of unmarked fish in the system, with total return being the sum of unmarked and marked animals.

## RESULTS AND DISCUSSION

## RETROSPECTIVE PATTERNS

When hierarchical models are used, there could be changes to the estimates of abundance of previous years as new data are added because the annual estimates of tag movement rates, trapnet efficiencies, and proportions of runs at barriers are influenced by information from all years through the hyperparameter distributions. When the mark and recapture data are highly informative, the estimates over time are expected to be stable. When this information is weak or absent, the annual estimates may vary as additional years of data are added.

Chaput (2010) used the hierarchical model assuming that the headwater barrier counts were indices of total returns to each corresponding branch. This model was applied sequentially to the data from 1998 to 2009, from 1998 to 2010 and from 1998 to 2011. Estimates of abundance by size group to the Miramichi River and to each of the Northwest and Southwest branches are shown in Tables 4a to 4c and Figures 3a to 3c.

For the Miramichi River overall, there is no retrospective pattern and no important changes in the estimates of small salmon returns (Fig. 3a). For large salmon, the estimates for the years 2004 to 2006 increased (by 13\% to 19\% from 2009 to 2011) due primarily to the addition of the 2011 data (Table 4a; Figure 3a).

The retrospective patterns for the estimates of abundance for the Southwest Miramichi are similar to those of the Miramichi overall with no important differences in small salmon estimates but higher abundance estimates for large salmon when the 2011 data are included for the 2004 to 2006 years (Table 4b; Figure 3b). For the Northwest Miramichi, small salmon abundance estimates are similar among model runs and large salmon abundance estimates are similar although there is a slight and consistent decrease in abundance estimates for 1998 to 2009 when data from 2010 and 2011 are used, but these differences are negligible when accounting for the uncertainty of the estimates (Table 4c; Figure 3c).

## REVISED MODEL FOR 2011

Following on recommendations from a previous review in March 2010 (Chaput 2010; DFO 2010), the counts at the headwater barriers in the Northwest Miramichi and in the Dungarvon River were assumed to be an index of the early run (prior to August 1) to each branch whereas the counts at the Juniper barrier in the Southwest Miramichi were considered to be an index of the run for the whole season. This choice is based on an analysis of tagged salmon recovered at the headwater barriers for the period 1995 to 2004 which indicated that $83 \%$ and $84 \%$ of the tags recovered at the Northwest Miramichi barrier and the Dungarvon River barrier, respectively, were from salmon tagged prior to August 1 (J. Hayward, DFO, unpublished data). Of the recaptured salmon at the Juniper barrier, $70 \%$ had been tagged prior to August 1.

In addition, the Juniper barrier has not operated as consistently during the year in 2010 and 2011 and the counts are considered partial counts and not exchangeable with the previous years. For this reason, the model used in 2011 excludes the Juniper barrier data for 2010 and 2011.

These changes in treatment of the barrier indices had minimal effect on the estimates of abundance for small salmon and large salmon from the Miramichi River overall, and for each of the branches (Tables 5a-c; Figures 4a-c). The median estimates for large salmon for 2011 for the Miramichi overall and the Southwest Miramichi are higher with the revised model structure
but the median value is contained within the interquartile range of the estimate uncertainty (Fig. 4a,-b). There are minimal difference in estimates for the Northwest Miramichi (Fig. 4c; Table 5c).

The 2011 version of the model was retained in all subsequent analyses.

## MODEL DIAGNOSTICS

## Prediction of recaptures at trapnets

The predicted versus observed recaptures of small salmon and large salmon at the SW Millerton, NW Cassilis, and the NW RedBank trapnets are summarized in Figure 5.

Overall, the hierarchical model adequately (within the 95\% B.C.I.) predicted recaptures by size group and trapnet location with a few discrepancies. In most cases, the observed recaptures were within the interquartile range (25th to 75th percentile) of the predicted recaptures (Fig. 5). Important discrepancies, with observed recaptures outside the 95\% B.C.I. range, were noted for recaptures of SW Miramichi lower trapnet large salmon at the SW Millerton trapnet in 2007 (one recapture versus median predicted recapture of 10), recaptures of SW Millerton tagged small salmon at the NW Red Bank trapnets in 2000 and 2002 (observed less than predicted in 2000, observed greater than predicted in 2002) (Fig. 5).

## Model convergence and posterior distributions

The tools provided in OpenBUGS were used to assess model convergence and posterior distributions (Spiegelhalter et al. 2010). A burn-in of 50,000 to 100,000 MCMC draws was used for small salmon and large salmon, respectively. Posterior distributions were summarized from a subsequent 20,000 MCMC draws using two chains and keeping every fifth MCMC draw. The history of the MCMC draws, the BGR (Gelman-Rubin statistic) plots and the posterior densities of the estimates for the total returns to the Miramichi River, as an example, are shown in Figure 6.

The BGR diagnostic is calculated when multiple chains of initial values are used. The basic idea is to generate multiple chains starting at over-dispersed initial values, and assess convergence by comparing within- and between-chain variability over the second half of those chains. The ratio $\mathrm{R}=\mathrm{B} / \mathrm{W}$ (where B is the width of the central $80 \%$ interval of the pooled chains and W is the average width of this interval within individual chains) should be greater than 1 if the starting values are suitably overdispersed; it will also tend to 1 as convergence is approached. R must converge to 1 and $B$ and $W$ should have converged to stability.

Convergence was considered to have been attained. The MCMC draws occurred over a stable range of values and the BGR plots indicate convergence over the sampling history (Fig. 6). The posterior distributions were unimodal and strongly defined relative to the uniform uninformative prior assumptions (Fig. 6). The 2011 posterior distribution estimate for large salmon was less smooth than in other years, suggesting that there was somewhat more relative uncertainty than for other years (Fig. 6).

## Shrinkage resulting from hierarchical modeling relative to annual models

Hierarchical models of the type described in this paper are proposed as a means of benefiting from experience in previous years (Rivot and Prévost 2002; Chaput 2010). Annual models treat
the mark and recapture experiments as if nothing was known about the parameters of interest, in particular the movement of fish between branches and the efficiency of the index trapnets. Under the hierarchical model structure, the information from other years can be considered as prior information, before the mark and recapture experiment is conducted. In the absence of useful information in a given year with which to estimate the parameters of interest, the prior information is used. The importance of this prior information versus the amount of information contributed by the annual experiment is described by the change in these estimates, termed shrinkage, based on an annual model that ignores all prior experience versus the hierarchical model.

The estimates of abundance from the hierarchical model have less uncertainty, expressed as the coefficient of variation, in all years and for both size groups (Fig. 7). For the estimates of abundance for the Miramichi, the hierarchical and annual estimates are similar for small salmon for 1998 to 2004 (there was a large amount of information in the annual mark and recapture experiments for those years) but the shrinkage is very important for the 2005 to 2011 estimation years (Fig. 7). The shrinkage for large salmon is less severe, in terms of the median value but the coefficient of variation is much lower from the hierarchical model estimates (Fig. 7).

For the Southwest Miramichi, the hierarchical and annual estimates for small salmon differ the most and the shrinkage is most important for the 2005, 2007, 2008 and 2010 assessment years (Fig. 7). Even if the median estimate of small salmon abundance for 2009 is similar for the two models, the coefficient of variation is greatly reduced (24\%) with the hierarchical model compared to the annual model (CV 111\%) (Fig. 7). For large salmon, estimates differ the most in 2005, 2007 and 2011 (Fig. 7).

For the Northwest Miramichi, estimates for large salmon are most different in 2005 (when the NW Red Bank trapnets did not operate), 2003, 2008 and 2010 (Fig. 7). For small salmon, estimates in 2005 were not reasonable with the annual model, and in other years, the estimates from the hierarchical model are generally higher than with the annual model (Fig. 7). Again, the CVs are much lower with the hierarchical model.

## RESULTS OF HIERARCHICAL MODELLING

## Estimates of movements of tagged fish between branches

As noted in previous assessments (Chaput 2010), there is movement of tagged fish between the Northwest and Southwest Miramichi branches. About 94\% of small salmon and large salmon tagged in the Southwest Miramichi at the Millerton trapnet were estimated to have stayed in the Southwest Miramichi (Table 6). The majority, 83\% for small salmon and 88\% for large salmon, of salmon tagged at the lower trapnets in the Southwest Miramichi are estimated to remain in the Southwest Miramichi (Table 6). The majority of small salmon tagged at the Northwest Miramichi trapnet at Cassilis remained in the Northwest Miramichi (84\%; Table 6) but an important percentage of the large salmon tagged from the Northwest Miramichi Cassilis trapnet moved to the Southwest Miramichi, ranging from 24\% to 46\% (median values) between 1998 and 2011 (Table 6). The reason for the higher movement rate of large salmon from the Northwest is unknown.

## Estimates of trapnet efficiencies

The Southwest Miramichi Millerton trapnet was estimated to have captured about 3\% of the large salmon run of the Southwest Miramichi in 2011 (95\% B.C.I. 1\% to 4\%) (Table 7). The
median values over the period 1998 to 2011 have ranged from $3 \%$ to $10 \%$. Over all years, the percentage of the run intercepted has a median value of 5\% and a 95\% B.C.I, of $1 \%$ to $11 \%$ (Table 7). The efficiency in 2011 for small salmon is almost twice the value of large salmon, about $6 \%$ ( $95 \%$ B.C.I. $4 \%$ to $9 \%$ ) with median values during 1998 to 2011 of $6 \%$ to $12 \%$. Overall, the percentage of the run of small salmon to the Southwest Miramichi captured at the Millerton trapnet has a median value of $9 \%$, with a $95 \%$ B.C.I. of $4 \%$ to $16 \%$ (Table 7).

The Cassilis trapnet in the Northwest Miramichi captures a higher percentage of the run of small salmon and large salmon than the Millerton trapnet in the Southwest Miramichi. In 2011, 9\% of the large salmon run in the Northwest Miramichi was captured at Cassilis (95\% B.C.I. 5\% to 15\%), a similar rate to that of small salmon (median 9\%; 95\% B.C.I. 6\% to 12\%) (Table 7). Overall, the Cassilis trapnet captures about $11 \%$ of the small salmon run to the Northwest Miramichi (6\% to 17\%) and 10\% of the large salmon run (4\% to 23\%).

## Estimates of proportions of returns going to headwater barriers

As indicated previously, the barriers in the Northwest Miramichi and at Dungarvon in the Southwest Miramichi are considered indices of the early runs (prior to August 1) to each branch.

Based on the estimated abundances of early run fish to each branch, the counts of the Northwest Miramichi barrier represent important proportions of the early run of both the small salmon and large salmon (Table 8). For small salmon, the median values ranged from 7\% to $26 \%$ of the annual early run returns and the overall percentage is estimated at $13 \%$ but it is highly variable among years (95\% B.C.I. 3\% to 34\%) (Table 8). For large salmon, the median values range from $8 \%$ to $37 \%$ of the annual early run returns and the overall percentage is estimated at $18 \%$ but is it also highly variable annually ( $95 \%$ B.C.I. $4 \%$ to 45\%) (Table 8).

Large salmon counts at the Dungarvon Barrier represented 1\% to 6\% of the annual early run return of large salmon and the overall percentage is estimated at $3 \%$ with a $95 \%$ B.C.I. range of $1 \%$ to $7 \%$ (Table 8). Small salmon have represented between $2 \%$ and $12 \%$ of the annual early run return with the overall percentage of $4 \%$ ( $95 \%$ B.C.I. range of 1\% to 11\%) (Table 8).

The Juniper barrier in the upper Southwest Miramichi is considered an index of the total run to the Southwest Miramichi. Over the period 1998 to 2009, the counts of small salmon have represented between $3 \%$ and $6 \%$ of the annual returns and the overall percentage is estimated at $4 \% ~(95 \%$ B.C.I. range of $2 \%$ to $8 \%$ ) (Table 8). For large salmon, the percentage of the total run which is estimated to migrate to the barrier has varied from $4 \%$ to $6 \%$ and the overall value is $5 \%$ ( $95 \%$ B.C.I. of $3 \%$ to $9 \%$ ). The coefficient of variation of the proportions of the total returns counted at the Juniper barrier (12\% to 24\%) are lower for large salmon than at the Dungarvon barrier (15\% to 29\%) and the Northwest Miramichi barrier (20\% to 33\%) but the CVs are similar among the three headwater sites for small salmon (12\% to $23 \%$ for Juniper; $13 \%$ to $23 \%$ for Dungarvon; $10 \%$ to $21 \%$ for the Northwest Miramichi).

In the absence of other information, the use of these barrier counts as indices of returns would result in estimates with large uncertainties.

## Estimates of returns by size group and branch

Estimates of returns by size group for the entire season and for the early run (prior to August 1) for 1998 to 2011 are presented for the Miramichi River overall in Table 9a, for the Southwest Miramichi in Table 9b and for the Northwest Miramichi in Table 9c.

Estimated returns of small salmon to the Miramichi in 2010 were about 53,000 fish and in 2011 about 46,000, the highest returns over the period 1998 to 2011 (Table 9a; Fig. 8a). Returns of large salmon in 2010 were estimated at just under 18,000 fish and about 34,000 fish in 2011, the 2011 estimated abundance is the highest of the 1998 to 2011 time series (Table 9a; Fig. 8a). Early run returns of small salmon in 2010 and 2011 were about 38,000 fish, the highest of the 1998 to 2011 time series whereas large salmon early run returns were 12,200 in 2010 and 24,600 in 2011 (Table 9a; Fig. 8a). The early run return in 2011 was about twice the run size of 2010 and from two to four times larger than the early run returns of 1998 to 2008 (Table 8a). There has been an important change in the proportion of the total return which is in the early portion of the run, with $65 \%$ or less for small salmon prior to 2008 and at $72 \%$ to $82 \%$ early run in the past four years (Table 9a). A more important change in proportion early run has been observed for the large salmon group; proportion early was $43 \%$ or less prior to 2007, rising to $50 \%$ in 2008 and at $68 \%$ to $85 \%$ in the past four years (Table 9a). The reasons for the change in run-timing are discussed by Douglas et al. (2012).

Estimated returns of small salmon to the Southwest Miramichi were 34,000 in 2010 and 31,700 in 2011, the two highest values over the 1998 to 2011 time period (Table 9b; Fig. 8b). Large salmon returns in 2010 were estimated at about 14,000 fish, within the range of values observed during 1998 to 2009 while returns in 2011 were estimated at 27,900 fish, the highest value of the time series (Table 9b; Fig. 8b). Early run small salmon returns in 2010 and 2011 were in the range of 25,000 to 26,000 fish, respectively, nearly twice the highest values estimated in most years during 1998 to 2009 (Table 9b, Fig. 8b). Early run large salmon were just under 9,000 fish in 2010, the third highest of the time series while in 2011, large salmon returns were 20,500 fish, the highest and by more than three times the value in most previous years since 1998 (Table 9b). As for the Miramichi overall, the early run of small salmon and large salmon has become a more important proportion of the total run to the Southwest Miramichi; $78 \%$ to $82 \%$ of the small salmon run and $69 \%$ to $89 \%$ of the large salmon run in the past four years (Table 9a).

In the Northwest Miramichi, small salmon returns in 2010 were about 17,800 fish, the highest of the 1998 to 2011 period, and in 2011 returns were about 13,600 fish, the third highest of the time series (Table 9c; Fig. 8c). Early run returns of small salmon in 2010 were the highest ( 12,800 fish) and returns in 2011 of 11,700 fish were the third highest values since 1998 (Table 9c; Fig. 8c). The proportion early in the Northwest has been quite variable over the 1998 to 2011 time period, 0.33 to 0.86 , with the proportion early being consistently high at between 0.72 and 0.86 in the past four years (Table 9c). For large salmon, the estimated return in 2010 was 3,400 fish, within the range of values from 1998 to 2009 while returns in 2011 were estimated at 5,100 fish, the second highest of the time series (Table 9c; Fig. 8c). Early run returns were estimated at 2,200 large salmon in 2010 and 3,700 large salmon in 2011, the two highest values of the time series (Table 9c; Fig. 8c). The early-run estimate for 2011 is higher than the estimated total return to the Northwest Miramichi in 10 of the 14 years (Table 9c; Fig. 8c). As for the small salmon, the proportion early run for large salmon has been highly variable, from 0.17 to 0.66 during 1998 to 2007 but has been between 0.64 and 0.75 in the past four years (Table 9c).

As a prior assumption of expected run size to each branch, one could consider the relative habitat areas (or conservation egg requirements) of the Southwest Miramichi and the Northwest Miramichi rivers (Appendix 1). The conservation egg requirement for the Southwest Miramichi is 88.1 million eggs, and for the Northwest Miramichi 40.3 million eggs. The Southwest Miramichi is therefore about twice the size of the Northwest Miramichi so the expected proportion of total run to the Miramichi River which would be to the Southwest Miramichi is 0.686 . The proportion
of the total Miramichi River small salmon returns which were estimated for the Southwest Miramichi have been equally often above and below this a priori value (Fig. 9). In contrast, the large salmon returns to the Southwest Miramichi were estimated to have comprised a higher proportion of the total in all years, except 2001, than would be expected based on river size alone (Fig. 9). The a priori value for the expected proportion of returns to each branch is based on the assumption that the salmon in each branch have similar characteristics and population dynamics, i.e. similar proportions sea age at maturity, similar sex ratio by size group, similar river age characteristics, and similar rates of egg depositions. Several of these including river age at smoltification, sex ratio especially in the small salmon, and achieved egg depositions are known to differ between the two branches. Proportion of conservation egg requirements achieved in the two branches is a better indicator of relative performance.

## RECOMMENDATIONS FOR FURTHER WORK

A few of the recommendations described in Chaput (2010) to improve the hierarchical model were implemented in this assessment. One of the recommendations was to treat the headwater barrier data as an index of early run size and in particular as an index of escapement rather than returns. This was only partially considered. In the absence of harvest data from the recreational fishery and incomplete data from the aboriginal fisheries, it is not possible to estimate escapement. In the absence of angling data post 1997, the exploitation rates and harvests would have to be estimated from the historical data and applied to the years when the angling data are unavailable. Consequently, the barrier counts were treated as an index of returns which assumes that the removals were a constant proportion of the returns over all years.

Another recommendation was to treat the angling data from the Northwest Miramichi crown reserve as an indicator of early-run size. The time series is complete back to 1984 when catch and release measures for large salmon were introduced. It is feasible to estimate the catch rates from the Crown Reserve angling stretches using the estimates of annual catch and effort and estimates of total early run returns. This would be of benefit for the years prior to 1998 when the mark and recapture program was developing in each branch and for the years prior to 1992 when the monitoring program was focused on one trapnet in the lower portion of the Miramichi. Catch rates, expressed as proportion crown reserve angling catches of the total early run estimate to the Northwest Miramichi, have varied from 0.07 to 0.43 for small salmon, 0.03 to 0.23 for large salmon, over the period 1998 to 2011. This addition to the model will be attempted at a later time.

Finally, it was recommended that the historical time series for the Miramichi be re-analyzed using the hierarchical model. The time series from 1984 to the present could be examined first as it represents the years post commercial fishery closure. Angling data from the two branches could also be used for the years when they are available (1984 to 1995, 1997). The model should incorporate the information on effort to estimate exploitation rates. Preliminary analyses of this were attempted but further work including diagnostics is required.

## ACKNOWLEDGEMENTS

The field operations and data management which are the foundation of this assessment were contributed by staff from DFO Science program in the Miramichi River (in alphabetical order): John Hayward, Dave Moore and Joe Sheasgreen. Workers from Eel Ground First Nation operated the trapnet and tagged fish from the lower trapnets in the Southwest Miramichi. Workers from Metepanagiag (Red Bank) First Nation operated and sampled fish from the upper trapnets in the Northwest Miramichi. A large number of students over the years, generously supported by the Northumberland Salmon Protection Association, assisted in the summer field operations and field support in the fall was provided on contract by the Miramichi Salmon Association.

Figure 8b. Returns total and for the early run of small salmon (upper panel) and large salmon (lower panel) for the Southwest Miramichi River, 1998 to 2011. Based on the version 2011 model.

Figure 8c. Returns total and for the early run of small salmon (upper panel) and large salmon (lower panel) for the Northwest Miramichi River, 1998 to 2011. Based on the version 2011 model.

Figure 9. Estimated (based on median value) proportion that Southwest Miramichi returns are of the total returns to the Miramichi River, by small salmon and large salmon, 1998 to 2011. The solid horizontal line, at 0.686 , is the proportion Southwest of the conservation egg requirements for the Northwest and Southwest branches.

## Appendix 1. Mark and recapture models applied to the Miramichi adult salmon data.

The models are developed in a Bayesian framework in which prior information of the quantities of interest are updated using observations and likelihoods for those observations (Fig. A1-1). Acronyms, observations, likelihoods and priors are described in Tables A1-1 to A1-4.

The quantities of interest for the assessment are the annual returns of salmon by size group to the Northwest and Southwest branches (TotSW; TotNW) and to the Miramichi River overall. This cannot be measured directly as there is no complete enumerating system on this river. Expert opinion provides a range for the possible run size to this river, based on wetted area for juvenile production and an assumed population dynamic for salmon. The conservation spawning requirement for the Miramichi River and its two branches is based on a measure of wetted area for juvenile production and an egg deposition rate of 240 eggs per $100 \mathrm{~m}^{2}$ (Chaput et al. 2001). Based on average biological characteristics, the conservation requirements are about 16,000 large salmon for the Southwest Miramichi and 7,300 fish for the Northwest Miramichi. Recruits per spawner of 5:1 would be very high production for Atlantic salmon and a return of 100, 000 large salmon would be an upper limit for the Miramichi. Catches of small salmon at trapnets are generally higher than for large salmon and returns of 200 to 300 thousand small salmon would be an upper limit to the maximum returns expected in each branch. The Southwest Miramichi has twice the juvenile production area of the Northwest Miramichi and returns to the former are expected to be about twice those of the latter.

|  | Habitat area <br> $\left(\right.$ million $\left.\mathrm{m}^{2}\right)$ | Egg requirement <br> (millions) | Fish required |  |
| :--- | :---: | :---: | :---: | :---: |
|  |  | 132 | Large salmon | Small salmon |
| Miramichi River | 1.1 | 3 | 23,600 | 22,600 |
| Main Miramichi | 36.7 | 88.1 | 554 | 531 |
| Southwest Miramichi | 16.8 | 40.3 | 15,730 | 15,063 |
| Northwest Miramichi |  | 7,316 | 7,006 |  |

Uninformative uniform prior distributions were chosen for the returns of small salmon and large salmon to each branch.

| Branch | Size group | Distribution | Lower | Upper |
| :---: | :---: | :---: | :---: | :---: |
| Southwest | Small | Uniform | 1,000 | 500,000 |
|  | Large | Uniform | 1,000 | 200,000 |
| Northwest | Small | Uniform | 100 | 300,000 |
|  | Large | Uniform | 100 | 100,000 |

To update the prior information on returns, we can use several indicators of salmon abundance in Miramichi including catches at estuary trapnets and counts at headwater protection barriers. All of these are partial measurements of the total returns. The objective is to estimate the raising factors of these indicators to the total returns of salmon.

The indicators of abundance for the Miramichi were modelled as having come from a binomial process with the successes (samples or catches) dependent on the number of trials (total run of fish to the river) and the probability of success (the proportion of the total run which is sampled or caught) (Table A1-2; A1-4).

The hierarchical model structure allows the transfer of information over all years. In the following simple example:
$\left[\operatorname{catch}_{\mathrm{i}} \mid \mathrm{p}_{\mathrm{i}}, \mathrm{N}_{\mathrm{i}}\right] \sim \operatorname{binomial}\left(\mathrm{p}_{\mathrm{i}}, \mathrm{N}_{\mathrm{i}}\right)$
 size in year $i$ is binomial with parameters $p_{i}, N_{i}$
$p_{i} \sim \operatorname{beta}(a, b)$
$p_{i}$ is beta distributed with parameters $a$ and $b$
$p_{i}$ is the "true" probability of capture (trapnet efficiency) in year i and the $p_{i}$ 's are a random sample (over years) from a common population distribution. The trapnet efficiencies are assumed to be similar but not identical. The beta(a,b) prior describes the distribution of fishing efficiency among the years. A joint probability model for the entire set of parameters $\left(p_{i}, a, b\right)$ is developed and prior distributions are assigned to $a$ and $b$.

Rather than setting priors directly on $a$ and $b$, priors were set on the mean and variance of the Beta(a, b) distribution (Rivot and Prevost 2002). After alternate variable transformation, an uninformative prior distribution which is essentially uniform over the interval 0 to 1 for the $p_{i}$ 's is obtained from:
$E \sim \operatorname{beta}(1.5,1.5)$
$\mathrm{u} \sim \operatorname{beta}(1,10)$
$a_{i}=E(1-u) / u$
$b_{i}=(1-E) *(1-u) / u$
$p_{i} \sim \operatorname{beta}\left(a_{i}, b_{i}\right)$
In annual models, neither the barrier count data nor the recreational fishing data are informative because the proportion of the run which goes to the barriers or is angled is estimated from the run size which is derived from the mark and recapture data. In the hierarchical model, the barrier data are used and an overall proportion of the run which goes to the barriers can be estimated over all the years with mark and recapture data. The overall proportion can then be applied to the years when no mark and recapture data are available. This is the same case for the recreational fisheries data.

The models were run using Monte Carlo Markov Chain with the Gibbs sampler in "OpenBugs" (Spiegelhalter et al. 2010).
