This series documents the scientific basis for the evaluation of aquatic resources and ecosystems in Canada. As such, it addresses the issues of the day in the time frames required and the documents it contains are not intended as definitive statements on the subjects addressed but rather as progress reports on ongoing investigations.

La présente série documente les fondements scientifiques des évaluations des ressources et des écosystèmes aquatiques du Canada. Elle traite des problèmes courants selon les échéanciers dictés. Les documents qu'elle contient ne doivent pas être considérés comme des énoncés définitifs sur les sujets traités, mais plutôt comme des rapports d'étape sur les études en cours.

Les documents de recherche sont publiés dans la langue officielle utilisée dans le manuscrit envoyé au Secrétariat.

#### Abstract

The status of the cod stock in Northwest Atlantic Fisheries Organization (NAFO) Subdivision 3Ps was assessed during a regional advisory process (RAP) held during October of 2011. Stock status was updated based upon information collected up to spring 2011. Principal sources of information available for the assessments were: a time series of abundance and biomass indices from Canadian winter/spring research vessel bottom trawl surveys, inshore sentinel surveys, science logbooks from vessels <35 ft, reported landings from commercial fisheries, oceanographic data, and tagging studies. Total landings for the 2010-2011 management year (April 1 to March 31) were 7,800 t or just $68 \%$ of the total allowable catch (TAC). Though this is the second consecutive year that the TAC was not fully taken, it is unusual. Industry participants indicated this discrepancy was primarily due to reduced profitability, additional market considerations, and some reduction in fish availability offshore. The 2011-2012 fishery was still in progress at the time of the RAP with provisional landings to date totaling of $2,600 \mathrm{t}$. The removals through recreational fishing are unknown since 2007, but based on previous estimates are thought to be a small fraction ( $\sim 1 \%$ ) of the commercial landings.

A complex of stock components are exploited in Subdiv. 3Ps. Thus the impact of fishing at specific TAC levels on all components cannot be quantified. However, the Fisheries and Oceans Canada (DFO) research vessel (RV) survey covers most of the stock, and it is thought that survey trends broadly reflect overall stock trends.

The abundance and biomass indices from the 2011 DFO RV spring survey were both lower than those in 2010, and both are presently below the time-series (1983 to 2010) average. The 2006 year-class is estimated to be well above average, and survey results for this year-class are comparable to the 1997 and 1998 year-classes, each of which contributed to stock growth and supported commercial fisheries for several years. The gillnet catch rates from inshore sentinel surveys and logbooks for vessels < 35 ft suggest stability. However, recent line-trawl catch rates from these sources indicate decline.

Spawning stock biomass (SSB) estimated from a survey based cohort model decreased in recent years and was estimated to be below the limit reference point (LRP) during 2008 and 2009. Thereafter, SSB has increased, and in 2011 is estimated to be above the LRP, with a low probability of being below the LRP (0.08). A one year projection to 2012 using the cohort model indicated that survey SSB will continue to increase if total mortality is similar to current values (i.e., within $\pm 20 \%$ ). This increase is due to the recruitment of the relatively strong 2006 year class (YC) to the spawner biomass. The projection also indicated that the probability of being below the LRP in 2012 is low ( 0.02 to 0.09). A three year projection to 2014 indicates subsequent declines in both total biomass and spawning biomass, and in 2014 the probability of being below the LRP ranges from 0.03 to 0.56 , depending upon the assumed mortality.

## RÉSUMÉ

L'état du stock de morue dans la sous-division 3Ps de l'Organisation des pêches de l'Atlantique Nord-Ouest (OPANO) a fait l'objet d'une évaluation lors d'un processus d'évaluation régionale (PER) en octobre 2011. L'état du stock a été mis à jour à partir des données recueillies jusqu'au printemps 2011. Voici les principales sources de données utilisées dans les évaluations : une série chronologique d'indices d'abondance et de biomasse obtenus par des relevés au chalut de fond effectués à l'hiver et au printemps au moyen d'un navire de recherche canadien, des relevés par pêches sentinelles côtières, des journaux de bord des navires de recherche scientifique de < 35 pi et les débarquements signalés des pêches commerciales, les données océanographiques, ainsi que des études de marquage. Les débarquements de l'année de gestion de 2010-2011 (du $1^{\text {er }}$ avril au 31 mars) ont totalisé 7800 tonnes ou juste $68 \%$ du total autorisé des captures (TAC). Même s'il s'agit de la deuxième année consécutive où le TAC n'a pas été atteint, cela reste inhabituel. Les participants de l'industrie ont signalé que cette anomalie était due surtout à une réduction de la rentabilité, à d'autres considérations relatives au marché et à la diminution de la disponibilité des poissons dans les zones extracôtières. Au moment du PER, la saison de pêche 2010-2011 était toujours en cours, et les données provisoires sur les débarquements totaux s'établissaient à 2600 t . On ignore le nombre de prises dans le cadre de la pêche récréative depuis 2007, mais, d'après les estimations précédentes, on croit qu'il représente une faible fraction ( $\sim 1 \%$ ) des débarquements commerciaux.
Un ensemble de composantes du stock de morue est exploité dans la sous-division 3Ps. En conséquence, l'impact de la pêche à des niveaux de TAC particuliers sur toutes les composantes ne peut pas être quantifié. Cependant, le relevé effectué par le navire de recherche de Pêches et Océans Canada (MPO) couvre presque tout le stock, et l'on croit que les tendances observées reflètent généralement les tendances globales du stock.
Les indices d'abondance et de biomasse du relevé du printemps 2011 du navire de recherche du MPO étaient inférieurs à ceux de 2010 et se situent actuellement en dessous de la moyenne de la série chronologique de 1983 à 2010. On considère que la classe d'âge de 2006 est bien au-dessus de la moyenne et les résultats du relevé pour cette classe sont comparables à ceux des classes des années 1997 et 1998, qui avaient contribué à la croissance du stock et alimenté la pêche commerciale pendant des années. Les taux de prise des relevés sentinelles au filet maillant dans les eaux côtières ainsi que les journaux de bord des navires de < 35 pi indiquent une certaine stabilité. Cependant, les taux de prise récents à la palangre que donnent ces mêmes sources indiquent un déclin.
La biomasse du stock reproducteur (BSR), estimée à partir d'un modèle de cohorte basé sur les relevés, a diminué ces dernières années et se situerait, selon les estimations, en dessous du point de référence limite ( PRL ) pendant 2008 et 2009. Après, la BSR a augmenté et on estime qu'elle se situe au-dessus du PRL en 2011, avec une faible probabilité $(0,08)$ qu'elle soit en dessous. Une projection d'un an jusqu'en 2012 établie à l'aide du modèle des cohortes a révélé que la BSR dérivée des relevés continuera de s'accroître si la mortalité totale demeure près des valeurs actuelles (c.-à-d. $\pm 20 \%$ ). Cette augmentation est causée par le recrutement de la classe d'âge relativement abondante de 2006 dans la biomasse reproductrice. La projection indique également que la probabilité que la BSR soit inférieure au PRL en 2012 est faible (de 0,02 à 0,09 ). Une projection de trois ans jusqu'en 2014 indique que la biomasse totale et la biomasse reproductrice déclineront par la suite et la probabilité qu'elles se situent en deçà du PRL en 2014 varie entre 0,03 et 0,56 , en fonction de la mortalité présumée.

## INTRODUCTION

This document gives an account of the 2011 assessment of the Atlantic Cod (Gadus morhua) stock in Northwest Atlantic Fisheries Organization (NAFO) Subdiv. 3Ps located off the south coast of Newfoundland (Figs. 1 and 2). The history of the cod fishery in Subdiv. 3Ps and results from other recent assessments of this stock are described in previous documents (see Brattey et al. 2007, 2008; Healey et al. 2011 and references therein). A regional assessment meeting was conducted during October 2011 (DFO 2012). Participants included DFO scientists, a scientist from the French Research Institute for Exploitation of the Sea (IFREMER, France), DFO fisheries managers, government officials from the province of Newfoundland and Labrador, fishing industry representatives, and a representative of World Wildlife Fund (Canada).

Various sources of information on Subdiv. 3Ps cod were available to update the status of this stock. Commercial landings through September 2011 were available, though catch at age was only updated to 2010 as the 2011 fishery and sampling thereof were ongoing. The results of the DFO research vessel survey during April 2011 was reviewed in detail and compared to previous survey results. Additional sources of information included science logbooks for vessels $<35 \mathrm{ft}$ ( 1997 to 2010), inshore sentinel surveys from 1995 to 2010 (Maddock Parsons 2013), and recaptures of tagged cod (received as of October 2010) from tagging conducted in Subdiv. 3Ps during 1997-2010 (Brattey and Healey 2006). A survey-based assessment model (Cadigan 2010) was used to smooth signals in the research vessel (RV) survey, and provided estimates of biomass, total mortality, and recruitment for that portion of the stock covered by the DFO RV survey. Short-term projections of these estimates under mortality similar to recent levels were also evaluated to advise on the management of this stock.

## ENVIRONMENTAL OVERVIEW

Oceanographic information collected during the spring DFO RV surveys indicated that near-bottom temperatures throughout Subdiv. 3Ps have warmed during 2009 to 2011 and are presently above average. As an example, the percentage of the survey area with bottom temperatures $\angle 0^{\circ} \mathrm{C}$ was near $0 \%$ in 2011, compared to almost $30 \%$ in 2007 and 2008. Survey catches of cod are generally lower in years when there are relatively large incursions of cold/fresh water from the eastern Newfoundland shelf. Furthermore, a significant positive correlation was found between bottom temperature and the survey abundance of cod in depths of 100 m or less. The areal extent of bottom water with temperatures $>3^{\circ} \mathrm{C}$ has remained relatively constant at about $50 \%$ of the total Div. 3P area, although actual temperature measurements show considerable inter-annual variability. The current conditions are comparable to those of the late 1970s and early 1980s when the stock was more productive.

## TOTAL ALLOWABLE CATCHES AND COMMERCIAL CATCH

## TOTAL ALLOWABLE CATCH (TAC)

A history of the total allowable catch (TAC) for this stock over 1959 to 2011 is presented in Table 1 (see also Fig. 3). This stock was subject to a moratorium on all fishing from August 1993 to the end of 1996. Excluding these years, the magnitude of the TAC has varied considerably over time, ranging from $70,500 t$ in 1973, the initial year of TAC regulation, to $10,000 t$ in 1997. The TAC for the past three seasons has been constant at 11,500 t. Under the terms of the 1994 Canada-France agreement, the Canadian and French shares of the TAC are $84.4 \%$ and $15.6 \%$, respectively.

## COMMERCIAL CATCH

Catches (reported landings) from Subdiv. 3Ps for the period 1959 to September $30^{\text {th }}, 2011$ are summarized by country and separately for fixed and mobile gear in Table 1 and Figs. 3a and 3b. Prior to the moratorium, Canadian landings for vessels $<35 \mathrm{ft}$ were estimated mainly from purchase slip records collected and interpreted by Statistics Division, Fisheries and Oceans Canada. Shelton et al.
(1996) emphasized that these data may be unreliable. Post-moratorium landings for Canadian vessels $<35 \mathrm{ft}$ have come mainly from a dock-side monitoring program initiated in 1997. Landings for Canadian vessels >35 ft come from logbooks. Non-Canadian landings (only France since 1977) were compiled from national catch statistics reported by individual countries to NAFO. In recent years, the provisional information for landings by France are provided directly by French government officials. Recent entries in Table 1 are designated as provisional until final catch statistics are available.
Cod in the Subdiv. 3Ps management unit was heavily exploited in the 1960s and early 1970s by non-Canadian fleets, mainly from Spain and Portugal, with reported landings peaking at about 87,000 t in 1961 (Table 1, Fig. 3a). After extension of Canadian jurisdiction in 1977, cod catches averaged between 30,000 t and 40,000 t until the mid-1980s when increased fishing effort by France led to increased total reported landings, with catches increasing to about 59,000 t in 1987. Subsequently, reported catches declined gradually to $36,000 \mathrm{t}$ in 1992. Catches exceeded the TAC throughout the 1980s and into the 1990s. The Canada-France boundary dispute at this time led to fluctuations in the French catch during the late 1980s. Under advice from the Fisheries Resource Conservation Council, a moratorium was imposed on all directed cod fishing in August 1993 after only 15,216 t had been landed. Access by French vessels to Canadian waters was restricted in 1993.

During the 2010 calendar year, total reported landings were 8,299 t with the Canadian inshore fixed gear sector accounting for $5,244 \mathrm{t}$ ( $63 \%$ ) of the total (Table 1). Total landings for the 2010-2011 management year (April 1-March 31) were $7,800 \mathrm{t}, 68 \%$ of the $11,500 \mathrm{t}$ TAC. Though this is the second consecutive season in which the full TAC was not landed (77\% of the TAC landed during the previous season), it is uncommon. Prior to the 2009-2010 season, the TAC had been fully utilized if not exceeded in each year since Canadian jurisdiction was extended in 1977 (excluding moratorium). Industry participants at the 2010 and 2011 assessment indicated several reasons contributing to this shortfall, but primarily it was thought to be due to a large reduction in prices, additional market considerations and a reduction in the availability of large fish offshore during winter 2010. Preliminary landings data for 2011 to September $30^{\text {th }}$ totaled 4,248 t. Although the 2011-2012 fishing season is incomplete, these totals to date are again relatively low due to reductions in fishing effort (DFO 2011) and it is unlikely that the full TAC will be landed.

Since 1997, most of the TAC has been landed by Canadian inshore fixed gear fishermen (where inshore is typically defined as Unit areas 3Psa, b, and c; refer to Fig. 1), with remaining catch taken mainly by the mobile gear sector fishing the offshore, i.e., Unit areas 3Psd, e, f, g, and h (Table 1, Fig. 3a, and 3b). This general pattern has continued since the fishery reopened in 1997, but there has been a slight increase in landings from offshore unit areas due to some smaller fixed gear vessels redirecting their effort to offshore fishing areas. However, in both 2009 and 2010, some of these patterns differed as effort and landings were reduced.
Line-trawl ( = longline) catches dominated the fixed gear landings over the period 1977-1993, reaching a peak of over 20,000 t in 1981 and typically accounting for $40-50 \%$ of the annual total for fixed gear (Table 2, Fig. 4). In the post-moratorium period, line-trawls have accounted for $16-26 \%$ of the fixed gear landings. Gillnet landings increased steadily from about 2,300 tin 1978 to a peak of over 9,000 t in 1987, but declined thereafter until the moratorium. Gillnets have been the dominant gear used for the inshore catch since the fishery reopened in 1997, with gillnet landings exceeding $50 \%$ of the TAC for the first time in 1998. Gillnets have typically accounted for $70-80 \%$ of the fixed gear landings since 1998. Gillnets accounted for a lower percentage of the fixed gear landings in 2001 (60\%), partly due to a temporary management restriction in their use that was removed part way through the fishery following extensive complaints from industry. Gillnets are also being used extensively in the offshore areas in the post-moratorium period (see below). Cod trap landings from 1975 up until the moratorium varied considerably, ranging from approximately $1,000-7,000 \mathrm{t}$. Since 1998, trap landings have been reduced to negligible amounts (<120 t). Hand-line catches were a small component of the inshore fixed gear fishery prior to the moratorium (about 10-20\%) and accounted for about $5 \%$ of landings on average for the post-moratorium period. However, hand-line catch for 2001 shows a substantial increase (to $17 \%$ of total fixed gear) and this may reflect the temporary restriction in use of gillnets
described above. In 2009, the proportion of hand-line catch doubled and increased to almost $10 \%$ of the fixed gear catch as buyers paid a higher price for hook-caught fish than for gillnet landings. This increase has not been sustained in either 2010 (or in 2011 statistics to date).
A summary of reported landings for 2010 and for 2011 (to date) by month and unit area is provided in Table 3. In general, the spatial-temporal pattern is similar in to those of recent years. Inshore landings are limited in March and April, mostly arising from by-catch of cod in other offshore fisheries. The vast majority of landings from the inshore areas (Unit areas 3Psa,b,c) are taken in June to November, with highest landings in June and July, particularly in Unit area 3Psc.
In the offshore, monthly landings tended to be more variable among unit areas. The majority of the offshore catch is taken in 3Psh during January to March and from 3Psf over September to November, which combined account for $>70 \%$ of the offshore catch. Less than $10 \%$ of offshore landings occurred within April-August resulting from relatively low effort through the spring and summer.

The distribution of total catch (post-moratorium) among unit areas is illustrated in Fig. 5. The inshore (3Psa,b,c) has consistently accounted for most of the reported landings. These have typically been highest in Placentia Bay (3Psc), ranging from 2,700 t to almost 11,650 t with 28-51\% of the annual Subdiv. 3Ps catch coming from this unit area alone. This percentage had declined steadily over 19992005, but has increased in the most recent five years and is now presently $38 \%$ of the Subdiv. 3Ps total landings. Landings from 3Psa and 3Psb have been fairly consistent at about 1,100-3,200 t and generally between $7-12 \%$ and $9-18 \%$, respectively, of the annual total. Most of the offshore landings have come from 3Psh and 3Psf (Halibut Channel and the southeastern portion of St. Pierre Bank). The percentage of total landings from 3Psf declined considerably in 2008. Unit area 3Psg normally has the lowest landings of any unit area (<4\% of the annual total each year since 1997), but in 2010 catches in this area, though still low, exceeded those of areas 3Psd and 3Pse combined. During the first quarter of 2009, no month or unit-area breakdown of French catch is available though these landings were known to be taken from either unit area 3Psf or 3Psh (L. Yetman, Fisheries and Aquaculture Management Branch, DFO, St. John's; pers. comm.). The 2009 values illustrated in Fig. 5 do not include these catches and hence are not representative of all landings.
The 2011-2012 ( $1^{\text {st }}$ of April to $31^{\text {st }}$ of March) conservation harvesting plan places various seasonal and gear restrictions on how the Subdiv. 3Ps cod fishery in Canadian waters could be pursued. Full details of these measures, which differ among fleet sectors, are available from the DFO Fisheries and Aquaculture Management (FAM) branch in St. John's.

## CATCH-AT-AGE

Samples of length and age composition of Canadian catches were obtained from the inshore gillnet, line-trawl and hand-line fisheries and the offshore otter trawl, gillnet, and line-trawl fisheries by port samplers and fishery observers. Additional sampling was obtained from the sentinel fishery. Length and age sampling of the catches by French fleet (St. Pierre and Miquelon, SPM) are collected by IFREMER. These data are used to age-disaggregate the total landings into numbers of removals by age. During 2010, more than 48,500 length measurements of Canadian and French catches were taken. In addition, 4,800 otoliths from Canadian catches were taken to determine the age composition of the catches (Table 4). All age determinations for 2010 catch-at-age were made by Canadian technical staff. During the February/March 2009 zonal cod assessment, a research recommendation highlighted a need to further examine discrepancies in age determinations from French and Canadian technical staff. This exchange occurred during late 2009 with results reported by Healey et al. (2011b). A workshop to improve consistency between the interpretations by staff in each country is scheduled for the fall of 2012. Following this workshop, it is expected that aging information will again be provided by France.

Canadian sampling totals are lower than in previous years and resulted from both reduced landings and reduced sampling efforts. Despite these reductions, sampling was reasonably well distributed spatially and temporally across the gear sectors. Sampling of lengths and ages of the Canadian and French catches during January to March 2011 was also undertaken, but data were not available at the time of the assessment and will be considered in future years.
The age composition and mean length-at-age of commercial catches were calculated as described in Gavaris and Gavaris (1983). Where possible, monthly landings for each gear type were age disaggregated using length and age samples from that quarter of the year (from the same gear type) to yield the age composition of each component of the catch. The average weights were derived from a standard length-weight (wt) relationship where:

$$
\log (w t)=3.0879 * \log (\text { length })-5.2106 .
$$

Catch-at-age for all gears combined based on sampling of Canadian and French vessels in 2010 is summarized in Table 5 and also Fig. 6. As described previously, these data exclude recreational catches, the magnitude of which has been unknown since 2007. Previous estimates of recreational catches indicated the total was a relatively low compared to commercial landings.

The 2010 landings from all gears combined include a wide range of ages (ages 2-21). In 2010, much of the catch was comprised of younger, smaller fish, with $60 \%$ of the numbers caught aged 6 or younger (Table 5, Fig. 6a). The modal age in the 2010 catch was age 6 , with approximately 1.3 million individuals taken ( $34 \%$ of total by numbers; Fig. 6b). The 1997 and 1998 year classes, aged 13 and 12 years old in 2010, were the focus of the fishery for many years, and although they are outside of the range of gillnet selectivity (predominantly ages 5-9), they still comprised $9 \%$ of the landed weight. Annual contributions to the catch-at-age are illustrated using a standardized proportion at age figure (Fig. 6c). Over the longer time series of catch (1977 to 2010), changes in the age distribution of annual catches (reflecting differences in gear composition of the catch pre and post-moratorium described previously) are evident. In this figure, cohorts which are strongly indicated in the commercial catch are large grey circles, while those which are well represented in the catches are large black circles. Over the past decade, this clearly illustrates the significance of the 1997 and 1998 year-classes to the total catch along with the below average to average contribution from several successive year-classes. Commercial catches of the 2004 cohort thus far indicate the proportional contribution is larger than average (Fig. 6c, lower panel).
Detailed information on the catch from the first three months of 2011 was not available at the time of the assessment; most catches during January-March are typically taken by mobile gear in the offshore.

Catch at age for the three main gear types in 2010 show (Fig. 7) that all gears catch a range of ages, but the dominance of gillnet selectivity on ages $5-8$ is evident, whereas line-trawls caught a larger fraction of younger fish (mainly ages 4-7). Otter trawls indicate a relatively wide range of ages captured, though almost $50 \%$ of the catch numbers in 2010 were of ages 4 and 6 only.
A time series of catch numbers-at-age (ages 3-14 shown) for the Subdiv. 3Ps cod fishery from 1959 to 2010 is given in Table 6. For 2010, the ratio of the sum-of-products (catch numbers and catch weights) to the total reported landings is 0.97 . As noted in recent assessments (e.g. Brattey et al. 2008), there are discrepancies in the ratio of the sum of the product to landings over the 1959 to 1976 period and attempts have been made to clarify these discrepancies by checking for missing catch and by adding plus group catch, but neither of these adequately explained the discrepancies. Until these discrepancies are resolved, it is recommended that catch at age prior to 1977 not be used in population analyses.
The catch-at-age data indicate that in the pre-moratorium period the landings were dominated by young fish, typically aged 4-6, whereas in the post moratorium period slightly older ages (i.e., ages $5-8$ ) have been more common (Fig. 6c) which likely reflects the switch in dominant gears from line-trawl and traps to gillnet. Line-trawl and trap typically select younger fish than gillnets.

## WEIGHT-AT-AGE

Mean weights-at-age in the Subdiv. 3Ps fishery (including landings from the commercial and food fisheries and the sentinel surveys) are given in Table 7a and Fig. 8. Beginning of the year weights-at-age are given in Table 7b and Fig. 9. The mean weights-at-age are derived from the sampling of catches taken by several gears in various locations at various times of the year; the weights at age may therefore vary with season and gear, and possibly by geographic area.
For young cod (ages 3-6), weights-at-age computed in recent years tend to be higher than those in the 1970s and early 1980s (Table 7a; Fig. 8). The converse is generally true for older fish. Sample sizes for the oldest age groups (>10) have been low in recent years due to the relative scarcity of old fish in the catch. Notwithstanding this limitation, the weight-at-age for ages $11-14$ in the past 2 years have increased considerably. Interpretation of trends in weights-at-age computed from fishery data is difficult because of among-year variability in the proportion at age caught by gear, time of year, and location.

## SENTINEL SURVEY

The sentinel survey has been conducted in Subdiv. 3Ps since 1995 and there are now 16 complete years of catch and effort data (see Maddock Parsons 2013). Sentinel activity for 2011 was ongoing at the time of the assessment; this data will be reviewed in subsequent years. The sentinel survey continues to produce a time series of catch/effort data and biological information collected by trained fish harvesters at various inshore sites along the south coast of Newfoundland. Sentinel fishers typically fish a control and an experimental site; the location of the control site is fixed, whereas the location of the experimental site can change only within the local area. In 2010, there were 13 active sites in Subdiv. 3Ps, using predominantly gillnets ( $51 / 2^{\prime \prime}$ mesh) in unit area 3Psc (Placentia Bay) and line-trawls in 3Psb and 3Psa (Fortune Bay and west). One 31⁄4" gillnet was also fished at each of 4 sites in Placentia Bay one day per week. Fishing effort was less in 1999 ( 6 weeks), 2003 and 2004 (8 weeks each), than most other years ( $9-12$ weeks), but since 2005 an average of 10 weeks has been maintained. Most fishing takes place in fall/early winter. Maddock Parsons (2013) provides a time series of weekly average catch rates and annual relative length frequencies (number of fish at length divided by amount of gear). Catch rates for $51 / 2$ " gillnets in 2010 remained low and were similar to those recorded for 1999 to 2009. Line-trawl catch rates decreased in both 2009 and 2010; the 2010 result was the lowest in the time-series.
As in previous assessments, an age disaggregated index of abundance was produced for gillnet ( $51 / 2^{\prime \prime}$ mesh) and line-trawl sampling. There are insufficient data from the $31 / 4$ " gillnets to develop a standardized index for this gear.

## STANDARDIZED SENTINEL CATCH RATES

The catch from Subdiv. 3Ps was divided into cells defined by gear type ( $5 \frac{1}{2}$ " mesh gillnet and linetrawl), area (unit areas 3Psa, 3Psb, and 3Psc), year (1995 to 2010) and quarter. Age length keys (ALKs) were generated for each cell using fish sampled from both the fixed and experimental sites; however, only fish caught at the fixed sites were used to derive the catch rate indices. Length frequencies and ALKs were combined within cells. The numbers of fish at length are assigned an age proportional to the number at age for that particular cell length combination. Fish that were not assigned an age because of lack of information within the initial cell were assigned an age by aggregating cells until the data allowed an age to be assigned. For example, if there are no sample data in a quarter then quarters are combined to half year, half years are combined to year; if an age still cannot be assigned then areas are combined for the year. Since 2002, there are considerably fewer otoliths available for aging; annual sample sizes range between 248 and 464 otoliths per year from gillnet catches (compared to an average of 1,050 otoliths during 1995 to 2002). Sample sizes for line-trawl are more variable, and in 2010 just 702 otoliths were collected - which is relatively low. For line-trawl there were < 700 otoliths per year during 2003 and 2004, but the numbers increased to 1,132
otoliths during 2005 and to 1,160 during 2006. However, less than 1000 cod have been sampled from line-trawl effort in both 2007 and 2008. These variations are generally reflective of annual differences in the numbers of fish caught and decreased sentinel effort over time. However, there have been some changes in the proportion of sampled fished aged over the duration of the Sentinel program. Despite these decreases, there have been no major difficulties in aging the sampled catch. Further, the fraction of the catch sampled for age in recent years is comparable to earlier years.
Catch at age and catch per unit effort (CPUE) data were standardized using a generalized linear model to remove site and seasonal effects. For gillnets, only sets at fixed sites during June to November with a soak time between 12 and 32 hours were used in the analysis. For line-trawl, sets at fixed sites during June to November with a soak time less than or equal to 24 hours were used in the analysis. Prior to modeling, data are aggregated within a gear division site month year age cell. Zero catches were generated for ages not observed in a set as sets with effort and no catch are valid entries in the model. Note that catch rates from the sentinel fishery are expressed in terms of numbers of fish, rather than catch weight as was used in the analyses of logbook data. This complicates direct comparisons of the trends from Sentinel surveys to commercial catch rates.

A generalized linear model (McCullagh and Nelder 1989) was applied to the sentinel catch and effort data for each gear type. The number of fish caught in each set is assumed to have a Poisson distribution. A log link function was chosen, and the factors included in the model were both "nested effects": month is nested within site and age is nested within year. Fishing effort is included as an offset term in the model. In the present assessment, the model adequately fitted data from gillnets and line-trawls, and all effects included in the model were significant.

Trends in standardized total (ages 3-10 combined) annual catch rates, expressed in terms of numbers of fish, are shown in Fig. 10a. Gillnet catch rates declined rapidly from 1997 to 1999 then remained stable but low from 1999 through to 2010. For line-trawls, catch rates show a decline from 1995, but have been relatively stable with no clear trend from 1997 to 2010.

Two standardized annual catch rate at age indices were also produced in the present assessment, one for each gear type. The standardized gillnet and line-trawl catch rate at age indices for 1995 to 2010 are given in Table 8 and Fig. 10b. For gillnets, several year classes were well-represented in catches during 1995 to 1997 but these are replaced by weaker year classes in all subsequent years. It has been noted that the 1997 and 1998 year-classes contributed significantly to both the fishery and RV index for several years. However, it is noteworthy that these year classes did not yield improvements in the magnitude of sentinel gillnet catch rates over 2002 to 2006, when these yearclasses would have been within the peak selection range of $51 / 2^{\prime \prime}$ gillnets.
For line-trawls, catch rates-at-age in the beginning of the time-series were higher due to the 1989 and 1990 year classes. In 2000-2002, sentinel line-trawl catch rates improved for younger fish (3 and 4 year olds) as the 1997 and 1998 recruited to this index. Catch rates for older fish continued to decline. Both the 1997, and in particular, the 1998 year class were consistently measured by sentinel linetrawl. As noted previously, these year-classes contributed strongly to commercial catches for several years. In addition, the 1999 year class also appears reasonably strong at ages 45 then is generally below average for older ages. This year class is weak in sentinel gillnet and in other (mobile gear) indices. These year-classes were followed by several successive year-classes which were weaker; but catch rates of the 2004 year-class at ages 3-5 (in 2007-2009) are higher (Table 8). In 2006, linetrawl catch rates for all ages (3-10) increased, suggesting a year effect in the data rather than a change in stock size (Fig. 10).
Although the sentinel indices did not increase in magnitude as the 1997 and 1998 year-classes were available to these gears, the age composition of the standardized estimates indicates that the 1997 year-class was consistently detected in the sentinel gillnets (Fig. 10b). Conversely, the 1998 yearclass was consistently tracked by line-trawl sampling.

As described in recent Subdiv. 3Ps cod assessments, interpretation of the sentinel catch rate indices is difficult. Sentinel fisheries were free from competitive influences during 1995-1996 as the commercial fishery was closed. However, commercial fisheries may have had some disruptive influence on the execution of the sentinel fishery during since 1997, particularly in Placentia Bay. The concentration of fishing effort in Placentia Bay during the late-1990s, primarily with gillnets, may have had a negative influence on the sentinel gillnet catch rates. Competition with commercial fishers for fishing sites, local depletion, inter annual changes in the availability of fish to inshore, and shifts in the timing of sentinel fishing to accommodate periods of commercial fishing could all influence mean catch rates between years. The extents to which such effects influence catch rates are not fully understood. These issues also complicate the interpretations of relative year-class strength over the time-series. The decline in sentinel gill net catch rates after the fishery reopened in 1997 are consistent with the inshore catch rate data from science log books and the high estimates of exploitation from tagging in Placentia Bay. More recently, the index is consistently tracking the 2006 year-class, though the overall index has not shown increase. The line-trawl index indicates a strong contribution from the 2004 yearclass; indications of the 2006 year-class have been less consistent. This is in contrast to the RV index, which has shown the 2006 year-class to be well above average.

## SCIENCE LOGBOOKS (<35 FT SECTOR)

A new science logbook was introduced to record catch and effort data for vessels $<35 \mathrm{ft}$ in the re-opened fishery in 1997. Prior to the moratorium, the only data for vessels $<35 \mathrm{ft}$ came from purchase slips, which provided limited information on catch and no information on effort. Since the moratorium, catch information comes from estimated weights and/or measured weights from the dockside monitoring program. Catch rates have the potential to provide a relative index of temporal and spatial patterns of fish density, which may relate to the overall biomass of the stock. Prior to the fall assessment meeting, there were about 159,000 records in the database. As with the analysis of results from the Sentinel program, we consider data to 2010 only, and exclude the current (inprogress) year. The total number of records has declined over time even over multi-year periods having common TAC. In addition, the percentage of the total cod catch for the $<35 \mathrm{ft}$ sector represented in the logbooks has decreased over time, from about $70 \%$ in 1997 to about $50 \%$ in recent years.
We present a catch rate index for data pertaining to the inshore fishery, i.e., unit areas 3Psa, 3Psb, and 3Psc. An initial screening of the data was conducted and observations were not used in the analysis if the amount of gear or location was not reported (or reported as offshore / outside of 3Psa, 3 Psb or 3 Psb ), more than 30 gillnets were used, or $<100$ or $>4,000$ hooks were used on a line-trawl. Upper limits for the amount of gear considered are applied to eliminate outlying records and exclude $<1 \%$ of the available data for each gear type. As observed in previous assessments, preliminary examination of the logbook data indicated that soak time for gillnets is most commonly 24 hours with 48 hours the next most common time period. In comparison, line-trawls are typically in the water for a much shorter period of time - typically 2 hours with very few sets more than 12 hours.
The screening criteria described above have resulted in a substantial fraction of $<35 \mathrm{ft}$ catch not being available for analysis. For example, in 2010 only $16 \%$ of the $<35 \mathrm{ft}$ gillnet catch and $24 \%$ of the $<35 \mathrm{ft}$ line-trawl catch is included in the CPUE standardization. These values are lower than usual as data entry for 2010 logbooks was ongoing at the time of the assessment. A major contributor to this loss of information is an increasing portion of logbooks records with invalid entries for the location fished. This occurs when logbook entries do not record a fishing location as shown on the map included in this logbook. (These are denoted as fishing areas 29-37 and illustrated in Fig. 11a). Most of these instances are generated from logbooks which report the location fished as either "10" or "11" - these references correspond to "species fishing areas" (e.g., Lobster Area 10) which are relatively large and include more than one of the fishing locations illustrated in Fig. 11a. Therefore it is not possible to resolve these entries to the finer-scale areas indicated in the logbook, and, consequently, a substantial fraction of the catch and effort data from smaller vessels is excluded by our selection criteria.

As in previous assessments, effort was treated as simply the number of gillnets, or hooks for line-trawls (1000s), deployed in each set of the gear; soak times were not adjusted as the relationship between soak time, gear saturation and fish density is not known. Catch rates from science logbooks are expressed in terms of weight (whereas those from the sentinel fishery are expressed in terms of numbers); commercial catches are generally landed as head-on gutted and recorded in pounds; these were converted to whole weight (in kg) by multiplying by a gutted to whole weight conversion factor (1.2) and converting pounds to kilograms (2.203).

The frequency distribution of catches per set is skewed to the right for both gears (not shown). For gillnets, catches per set are typically 100 to 200 kg with a long tail on the distribution extending to about 2 t . The distribution of catches for line-trawls was similarly skewed.

The catch from Subdiv. 3Ps was divided into cells defined by gear type (gillnet and line-trawl), location (numbered 29-37, as described above) and year (1997 to 2010).

Initially, un-standardized CPUE results were computed and examined; in this preliminary analysis plots of median annual catch rate for gillnets and line-trawl were examined for each year-location. Catch rates for gillnets tend to be higher in areas 29-32 (Placentia Bay and south of Burin Peninsula) than elsewhere. The gillnet catch rates for 2010 were not markedly different from recent values (Fig. 11b). For line-trawl, most data come from areas west of the Burin Peninsula and the results in areas 29-33 are based on low sample sizes and show more annual variability. Line-trawl catch rates from areas 34-37 in 2010 were quite variable compared to those of the past few years.

Prior to modeling, the data were aggregated within each gear-year-month-location cell, and the aggregated data were weighted by its associated cell count. Catch per unit effort (CPUE) data were standardized to remove site (fishing area) and seasonal (month, year) effects. Note that sets with effort and no catch are valid entries in the model.

In the present assessment, the model adequately fitted data from gillnets and line-trawls and two standardized annual catch rate indices were produced, one for each gear type. All effects included in the model were significant.

Standardized gillnet catch rates declined over 1998 to 2000 and have subsequently been low but stable at approximately $20 \mathrm{~kg} / \mathrm{net}$ (Fig. 11c). For line-trawls, catch rates declined from $300 \mathrm{~kg} / 1000$ hooks in 1997 to a minimum of about $200 \mathrm{~kg} / 1000$ hooks during 2002. Values for 2003 to 2006 were progressively higher and the 2006 value is the largest estimated catch rate at $353 \mathrm{~kg} / 1000$ hooks. Subsequently, catch rates have declined, and the 2010 value of $247 \mathrm{~kg} / 1000$ hooks is near the timeseries average.

The observed trends in commercial catch rate indices for the inshore fishery are influenced by many factors. There have been substantial annual changes in the management plans in the post-moratorium period (Brattey et al. 2003). In addition, gillnets and line-trawls can at times be deployed to target local aggregations. For inshore fisheries, catch rates can also be strongly influenced by annual variability in the extent and timing of inshore as well as long-shore cod migration patterns. Similarly, the changes in management regulations, particularly the switch from a competitive fishery to individual quotas (IQs) and for some vessels the need to fish cod as by-catch to maximize financial return, can have a strong influence on catch rates that is unrelated to stock size (DFO 2006). Consequently, inshore commercial catch rate data must be interpreted with caution. Despite these issues, the initial declines in gillnet and line-trawl catch rates following the re-opening of the fishery in 1997 were cause for concern. The recent decrease in modeled catch rates for line-trawls since 2006 may in part be reflecting the reduced availability of the 1997 and 1998 year classes in the inshore catch, as the numbers of fish in these cohorts decline. Close inspection of the commercial catch numbers-at-age data has shown that the proportion of cod age 7 and older in the line-trawl catch has increased over 2002 to 2010. Modeled gillnet catch rates have shown no significant changes in recent years.

## INDUSTRY LOGBOOKS (>35 FT SECTOR)

Median annual catch rates by gear sector and unit area from log books of larger vessels (>35 ft sector) were not available for this assessment as data analysis could not be completed prior to the assessment meeting. Recent trends were documented by Healey et al. (2011a), and it is expected that this data set will be studied further in future assessments.

## TAGGING EXPERIMENTS

A project involving tagging of adult ( $>45 \mathrm{~cm}$ ) cod initiated in 1997 has continued through 2010. The purpose of the tagging study is to provide information on movement patterns of Subdiv. 3Ps cod as well as obtain ongoing estimates of exploitation rates on different components of the stock. However, for several reasons, tagging efforts in Subdiv. 3Ps have been much reduced over the 2004 to 2010 period. In particular, tag releases in 2008 to 2010 have been limited to Placentia Bay only, with variable sample sizes (395, 2,510, and 1,022 tagged cod released in 2008, 2009, and 2010, respectively). In contrast to previous years, it is no longer possible to estimate tagging-based exploitation rates across most of the stock area. A brief synopsis of current results and details from previous years are provided below. Approximately 300 tags have been returned annually over 2008 2010. The percentage of tag returns from participants in the recreational fishery over this time has ranged from $4-8 \%$. Sufficient numbers of tags have been returned to estimate annual reporting rates (fraction of captured tags returned) using mixed-effects logistic regression (Cadigan and Brattey 2008).

## ESTIMATES OF EXPLOITATION (HARVEST) RATE

The methods used to estimate average annual exploitation rates (harvest rates, in percent) for cod tagged in different regions of Subdiv. 3Ps are described in detail previously (Brattey and Cadigan 2004; Brattey and Healey 2003, 2004, 2005, 2006; Cadigan and Brattey 2003, 2006, 2008). During 2001-2005, the mean exploitation rate was relatively high for cod tagged in Placentia Bay (3Psc, 22$31 \%$ ) compared to those tagged in Fortune Bay (3Psb, 10-12\%), Burgeo Bank/Hermitage Channel (3Psd, 1-8\%) or offshore in Halibut Channel (3Psg/h, 2-6\%), respectively. Estimation of inshore exploitation during 2006 and 2007 was hampered by insufficient numbers of releases. Although estimates of inshore exploitation rates from the 2006 fishery were reported by Brattey et al. (2007), they noted that due to the lapse in inshore tagging during 2004-2006, these rates were only partial estimates.
Estimated mean exploitation rates for cod tagged in Placentia Bay have all been less than $14 \%$ over 2008 to 2010. This level of exploitation would usually be considered "reasonable". However, results on size-specific exploitation rate from recent releases showed that although exploitation has been low in Placentia Bay, exploitation rate increases considerably with fish length, particularly for those sizes which are fully selected by the fishery (approximately 65 cm ). Exploitation rates were compared for all fish $>45 \mathrm{~cm},>55 \mathrm{~cm}$, and for all releases $>65 \mathrm{~cm}$. In 2008, exploitation rates corresponding to these size classes were $7 \%, 9 \%$ and $13 \%$ respectively. Corresponding results for 2009 were $9 \%, 15 \%, 27 \%$, respectively, and in 2010 were $13 \%, 21 \%$ and $22 \%$ respectively. Despite the substantial change with size, particularly the results for $>65 \mathrm{~cm}$, none of the values appear to be excessively high. It is cautioned that the exploitation rates for 2009 corresponded to tagging activity shortly before the 2009 fishery with limited time for dispersal of tagged fish which likely biases the estimated exploitation. Also noteworthy is that the exploitation rates of 2010 were higher even though only two-thirds of the 2010/2011 TAC was taken.

Tagging in the offshore (unit area 3Psh) was last conducted in 2005, and exploitation rates can be estimated - and compared - throughout 1998 to 2007. Exploitation rates estimated from tagging in Halibut Channel from 2005 to 2007 increased compared to previous estimates. The 2005-2007 exploitation estimates were about 8\% per year, compared to estimates of 2-3\% over 1997-2004.

With respect to migratory patterns and stock distribution, the tagging results of 2007-2010 generally agree with previous findings (Brattey et al. 2001, 2002; Brattey and Healey 2004, 2005, 2006), and indicate restricted mixing of cod from different portions of the Subdiv. 3Ps stock area. The limited mixing of inshore cod in particular make it difficult to determine whether inshore indices are reflecting trends in the stock as a whole or mainly of inshore components of the stock. Trends in the indices differ between inshore and offshore and are difficult to reconcile with the tagging results. Tagging suggests lower exploitation in the offshore than most inshore areas, yet the DFO RV declined for several years over 2001 to 2008. In contrast, inshore indices (sentinel) have been stable for several years (albeit at a lower level than when the fishery opened in 1997), whereas tagging suggests that in some inshore areas such as Placentia Bay exploitation was relatively high ( $\sim 25 \%$ ) for several years. The discrepancy between trends in inshore/offshore abundance indices and tagging estimates of exploitation was previously noted in recent assessments and remains enigmatic and difficult to explain.

## RESEARCH VESSEL SURVEY

Stratified-random surveys have been conducted in the offshore areas of Subdiv. 3Ps during the winter-spring period by Canada since 1972 and by France over 1978 to 1992. The two surveys were similar with regard to the stratification scheme used, sampling methods and analysis, but differed in the type of fishing gear and the daily timing of trawls (daylight hours only for French surveys). Canadian surveys were conducted using the research vessels A. T. Cameron (1972 to 1982), Alfred Needler (1983 to 1984; 2009 to 2010), and Wilfred Templeman (1985 to 2008). From the limited amount of comparable fishing data available, it has been concluded that the three vessels had similar fishing power and no adjustments were necessary to achieve comparable catchability factors, even though the A.T. Cameron was a side trawler. Cadigan et al. (2006) found no significant differences in catchability for several species, including cod, between the Wilfred Templeman and Alfred Needler research vessels. Surveys by France were conducted using the research vessels Cyros (1978 to 1991) and Thalassa (1992) and the results are summarized in Bishop et al. (1994).

The Canadian research vessel surveys from 1983 to 1995 employed an Engel 145 high-rise bottom trawl. In 1996, research surveys began using the Campelen 1800 shrimp trawl. The Engel trawl catches for 1983 to 1995 were converted to Campelen 1800 shrimp trawl-equivalent catches using a length-based conversion formulation derived from comparative fishing experiments (Warren 1996; Warren et al. 1997; Stansbury 1996, 1997).
The stratification scheme used in the DFO RV bottom-trawl survey in Subdiv. 3Ps is shown in Fig. 12. Canadian surveys have covered strata in depth ranges to 300 fathoms since 1980. Five new inshore strata were added to the survey from 1994 (stratum numbered 779-783) and a further eight inshore strata were added from 1997 (numbered 293-300) resulting in a combined 12\% increase in the surveyed area. Beginning in the 2007 assessment, new indices using survey results from the augmented survey area were presented for the first time. Two survey time series can now be constructed from the catch data from Canadian surveys. To avoid confusion, throughout this document as well as the Science Advisory Report from the 2011 assessment meeting (DFO 2011), the index from the expanded surveyed area that includes new inshore strata is referred to as the "All Strata <300 fms" index and the time series extends from 1997 onwards, whereas the original smaller surveyed area is referred to as the "Offshore" survey index and the time series that incorporates a random stratified design extends from 1983 to present.
The results (in Campelen or Campelen-equivalent units) for the entire survey area are summarized by stratum in terms of numbers (abundance) (Table 9) and biomass (Table 10), for the period 1983 to 2010. The timing of the surveys, number of sets fished, and vessels used are provided in the table header. Fig. 13 illustrates both the number of days taken to complete the survey of Subdiv. 3Ps, and also number of survey sets completed each year. Due to extensive mechanical problems with the research vessel, the survey in 2006 was not completed: only 48 of 178 planned sets were completed.

During 2010, one stratum in Subdiv. 3Ps could not be completed: stratum 295 in Fortune Bay. This is not considered problematic as this stratum comprises just $1 \%$ of the surveyed area, and on average, has contributed about $1 \%$ to the annual abundance and biomass indices. In the tables of results, strata for which no samples are available were filled in using a multiplicative model (excluding 2006 survey results). The timing of the survey has varied considerably over the period. In 1983 and 1984 the mean date of sampling was in April, in 1985 to 1987 it was in March, and from 1988 to 1992 it was in February. Both a February and an April survey were carried out in 1993; subsequently, the survey has been carried out in April. The change to April was aimed at reducing the possibility of stock mixing with cod from the adjacent northern Gulf (Div. 3Pn4RS) stock in the western portion of Subdiv. 3Ps. The stock mixing issue is described in more detail in previous assessments (e.g., Brattey et al. 2007).

## ABUNDANCE, BIOMASS, AND DISTRIBUTION

A time series of trawlable abundance and biomass indices from DFO random stratified RV offshore survey is given in Fig. 14. The abundance and biomass index estimates from the 2011 survey were 55.3 million fish and 30.5 Kt . In the 2011 survey there was no major change in the distribution of survey catches. The strata with the largest catches in terms of biomass were 319 and 323 (together, these strata cover much of the Halibut Channel) and 308 (a portion of Burgeo Bank). Combined, these strata accounted for $40 \%$ of the biomass index and $29 \%$ of the abundance index for 2010. Although it is common for results from the Halibut Channel to comprise a significant fraction of the overall survey abundance and biomass results, mostly due to results from stratum 319, it is atypical to have large contributions from stratum 323 (north of stratum 319).

Trends in the abundance index and biomass index from the RV survey are shown for the offshore (i.e., index strata only: those strata of depth less than or equal to 300 fathoms, excluding the new inshore strata) and the all strata area (Fig. 14). Survey indices of cod in Subdiv. 3Ps are at times influenced by "year-effects", an atypical survey result that can be caused by a number of factors (e.g., environmental conditions, movement, degree of aggregation, etc.) which may be unrelated to absolute stock size. The time series for abundance and biomass from 1983 to 1999 show considerable variability, with strong year effects, for example, the 1995, 1997 and 1998 surveys compared to those from adjacent years. The 1995 estimate is influenced by a single large catch contributing $87 \%$ of the biomass index and therefore has a very large standard deviation. The 1997 survey values were the lowest observed in the time series, which goes back to 1983, being less than half of the 1996 index. The size composition of fish in the 1997 RV survey suggested that this survey did not encounter aggregations of older fish, yet these fish were present in the 1996 survey and in subsequent commercial, sentinel, and survey catches. It is also likely that either the 2008 or 2009 results (possibly both results) include year-effects.
The trawlable abundance index declined from 88.2 million in 2001 to 38.7 million in 2008, the longest period of consistent decline in the entire time-series. However, the index has increased since 2008 and the 2011 estimate is near the 1997 to 2011 average. The trawlable biomass estimate has been variable for much of the post-moratorium period, but as with abundance, the biomass index generally declined over 2001 to 2008. The biomass index also increased considerably between 2008 and 2009, from 20.5 Kt to 56.0 Kt - approaching a three-fold increase. Although the 2010 index was similar to 2009, the increase has not been sustained, with the 2011 value being $40 \%$ lower than the 2010 result. Detailed trends in trawlable abundance and biomass are generally difficult to discern from the survey indices due to high intra-annual variability. Excluding the 1995 and 1997 survey results would suggest the time series of biomass estimates can be broadly divided into three periods - highest during 1983 to 1990, lowest during 1991 to 1997, and intermediate to low values during the most recent period 1998 to 2011. The trends and degree of variability in the combined inshore/offshore survey are almost identical to those of the offshore survey in spite of the $12 \%$ increase in surveyed area; the only exception is in 2004 when the combined inshore/offshore survey shows higher biomass and abundance due mainly to a large estimate from inshore stratum 294 (see Tables 9 and 10).

To investigate whether there have been annual shifts in the distribution of the stock at the time of the survey, trends in the proportion of the total abundance observed in three different regions of the stock area were compared (Fig. 15). The areas were: the inshore (strata 293-298, and 779-783), the Burgeo area (Hermitage strata 306-309, and 714-716), and the eastern area (remaining strata). Data from the combined inshore/offshore survey were used and the Campelen trawl was fished in all these surveys. The proportions were variable, with typically $30-70 \%$ observed in the larger eastern area, $15-60 \%$ in the western area, and around 10-25\% in the inshore area; an exception was 2005 when almost $40 \%$ of the total abundance index was observed in the inshore, again due to a large estimate for inshore stratum 294. Much of this variation is resultant from year effects, often resulting from a small number of survey sets with very large catches. For example, the value for 1998 is high due to several large catches on Burgeo Bank and vicinity that may have included fish from the neighbouring northern Gulf (Div. 3Pn4RS) cod stock. The age-aggregated surveys in recent years do not give any strong indications of a significant influx of cod from the neighbouring Div. 3Pn4RS stock.

The spatial distribution of catches of cod during the 2011 survey was examined, for all ages combined (Fig. 16a, includes 2008 to 2010 for comparison) and separately for ages 1-12 (Fig. 16b to 16d). Previously it has been demonstrated (Brattey et al. 2007; Healey et al. 2011a) that during 1999 to 2010 cod were caught over a considerable portion of Subdiv. 3Ps with the largest catches typically in the southern Halibut Channel area, on Burgeo Bank and vicinity, and in the outer portion of Fortune Bay. During these years cod were consistently scarce in the deep water below the mouth of Placentia Bay and in the inner reaches of Hermitage Channel.

Distribution plots of age-disaggregated survey catches from the 2011 survey (Figs. 16 b-d) indicate that relatively small catches of 1 year old cod were measured across much of the survey area where cod are typically found. Due to their small size, one-year old cod are not fully selected by the trawl. Cod aged 2 years old were encountered more frequently, especially along the eastern edge of the stock boundary. Cod ages 3 years old were found over most of the surveyed area, with the relatively large catches of these age groups taken on Burgeo Bank and within the Halibut Channel. The magnitude of the of catches of cod aged 4-9 year old in 2011 decrease considerably with age, and only small catches of these age groups were found outside of Burgeo Bank, the Hermitage Channel, or the Halibut Channel. Catches of cod in 2010 aged 10 or older were infrequent and far fewer fish were caught than in the recent past. Catches of these older fish are almost exclusively within the Halibut Channel.

## AGE COMPOSITION

Survey numbers at age are obtained by applying an age-length key to the numbers of fish at length in the samples. The current sampling design for cod in Subdiv. 3Ps requires that an attempt be made to obtain two otoliths per centimeter from each of the following locations: Northwest St. Pierre Bank (strata 310-314, 705, 713), Burgeo Bank (strata 306-309, 714-716), Green Bank-Halibut Channel (strata 318-319, 325-326, 707-710), Placentia Bay (strata 779-783) and remaining area (strata 315317, 320-324, 706, 711-712). This spatial stratification ensures sampling is distributed over the surveyed area. The otoliths are then combined into a single ALK and applied to the survey data. The resulting estimates of age-disaggregated mean numbers per tow are given in Table 11a. These data can be transformed into trawlable population abundance at age by multiplying the mean numbers per tow at age by the number of trawlable units in the survey area. This is obtained by dividing the area of the survey by the number of trawlable units. For the "offshore" survey in Subdiv. 3Ps, the survey area is 16,732 square nautical miles including only strata out to 300 fathoms (and excluding the relatively recent inshore strata added in 1997). The swept area for a standard 15 minute tow of the Campelen net is 0.00727 square nautical miles. Thus, the number of Campelen trawlable units in the Subdiv. 3Ps survey is $16,732 \div 0.00727=2.3 \times 10^{6}$. For the expanded survey area, there are approximately $2.7 \times 10^{6}$ trawlable units.
The mean numbers per tow at age in the DFO RV survey for the "offshore" index is given in Table 11a and results for ages 1-15 are shown in the form of standardized "bubble" plots in Fig. 17. Cod up to 20
years old were not uncommon in survey catches during the 1980s, but the age composition became more contracted through the late 1980s and early 1990s. In the 2011 survey, the number of fish age 7 and older is relatively low, consistent with results of recent years. The 2006 year-class, was measured as being much greater than average in each of the 2007 to 2010 surveys, and was primarily responsible for the considerable increase in the abundance index over that time. However, in 2011, the 2006 year-class (age 5) is near the time-series average. A more quantitative analysis of recruitment is given later.

Overall, the age composition of survey catches has expanded slightly in recent years with ages up to 17 years represented; however, the age structure remains somewhat contracted relative to the mid1980s with presently very few fish older than age 12.

## SIZE-AT-AGE (MEAN LENGTH AND MEAN WEIGHT)

The sampling protocol for obtaining lengths-at-age and weights-at-age has varied over time (Lilly 1998), but has consistently involved stratified sampling by length. For this reason, calculation of mean lengths and weights included weighting observations by population abundance at length (Morgan and Hoenig 1997), where the abundance at length ( 3 cm size groups) was calculated by areal expansion of the stratified arithmetic mean catch at length per tow (Smith and Somerton 1981). Only data from 1983 onward are presented.

Mean lengths-at-age were updated using the 2011 survey data (Table 12; Fig. 18). For ages older than age 3 there was a general decline in length-at-age from the early 1980s to the mid-1990s (Fig. 18a). For most ages there was an increase in length-at-age from the mid-1990s through the mid2000s, but data from 2007 to 2011 surveys suggest that mean length at age for ages 3-8 has been lower in most years than the mid-2000s.

Annual variation in mean length at age was examined by analyzing deviation from the average as a proportion over the time series for each age. The average mean length at age from 1983 to 2011 was calculated. At each age, mean-standardized deviations were calculated by subtracting the time-series mean from the annual observations and dividing this by the mean. These deviations were examined for a significant year effect using year as a class variable in a general linear model. Ages 3 to 9 were included. There was significant interannual variation in the deviation from mean length at age ( $\mathrm{F}=3.6$, $\mathrm{df}=27,195, \mathrm{P}<0.0001, \mathrm{r}^{2}=0.37$ ). Mean length at age was greater than average in the mid1980s. It showed a declining trend until the mid-1990s when it was below average. Mean length at age subsequently increased. Length at age has been generally lower in the last four years (Fig. 18b). Multiple comparisons based on least squares means were used to determine significant differences among years. Mean length at age was lower in 2011 than all but four years and significantly lower than in 2010. Growth from one year to the next (length increment) was also examined. First the effect of age on length increment was removed using a general linear model. The residuals from this model were then examined for a significant year effect using a generalized linear model with an identity link and a normal distribution. The amount of annual growth in length (growth increment) from 2010 to 2011 was also amongst the lowest in the time series (Fig. 18c).
Values for mean weight at age were updated with data from the 2011 survey (Table 13; Fig. 19a). There was a general decline in weight-at-age from the early 1980s to the mid-1990s (Fig. 19a). There was an increase in weight-at-age from the mid-1990s through the mid-2000s, but data from 2007 to 2011 surveys suggest that mean weight-at-age has been lower than the mid-2000s.
There was significant interannual variation in the proportion deviation from mean weight-at-age ( $\mathrm{F}=2.7, \mathrm{df}=27,195, \mathrm{P}<0.0001, \mathrm{r}^{2}=0.30$ ). Mean weight-at-age was greater than average in the mid1980s and generally declined until the mid-1990s (Fig. 19b). The lowest mean weights-at-age were observed in 1994-1995 and these were significantly different from 1983 to 1986. As with mean length-at-age, mean weights-at-age increased after that time until about 2000. In recent years, 2008 had lower mean weight-at-age than the 1983-1986 period and 2011 was lower than 1984 and 1986, but not lower than 2010.

## CONDITION

Relative gutted condition (relative K) and relative liver condition (relative LK) were calculated from survey data. It has been shown that the timing of the survey affects estimates of condition for Subdiv. 3Ps cod (Lilly 1998) and so only estimates from April surveys beginning in 1993 were estimated. A length gutted weight relationship was estimated, and the condition index is then observed condition divided by the condition predicted from the length weight regression for a fish of that length. Relative liver condition was calculated in a similar fashion using a liver weight length regression. Interannual variation in condition was analyzed using a generalized linear model with an identity link with a gamma distribution. Relative K increased until 1998, followed by a period of lower condition up until 2004 and very low condition in 2008 to 2010 (Fig. 20). Relative K in 2011 was about average and significantly lower than only 1998 and 2005. Estimates of relative K in 2008 to 2010 are significantly lower than estimates from the late 1990s and mid 2000s. Estimates of relative liver condition in 2010 are lower than all but those from 1993 to 1994, and estimates from 2008 are lower than all but 1995. Estimates from 2011 are higher than those from 2008 and 2010 but still lower than seven of the 11 years from 1997 to 2007. These results indicate that condition in recent years has been low compared to most of the years since the mid-1990s.

In conclusion, length at age has been generally lower in the last four years. Mean length at age was lower in 2011 than all but four years since 1983 and significantly lower than in 2010. The amount of annual growth in length (growth increment) from 2010 to 2011 was also amongst the lowest in the time series. Mean weights-at-age in 2011 were similar to the 2010 values, and were lower than the highs of the mid-1980s. Body condition in 2011 was about average, while liver condition was below most of the values from 1997 to 2007.

## MATURITY AND SPAWNING

The sampling design used to gather biological data to study maturation trends and an overview of recent maturity and fecundity research relating to Subdiv. 3Ps cod can be found in Brattey et al (2008).

Annual estimates of age at 50\% maturity (A50) for females from the Subdiv. 3Ps cod stock, collected during annual winter/spring DFO RV surveys, were calculated as described by Morgan and Hoenig (1997). Trends in age at $50 \%$ maturity are shown in Fig. 21a (only cohorts with a significant slope and intercept term are shown); parameter estimates and associated standard errors for the 1954 to 2006 cohorts are given in Table 14 and the model did not adequately fit the data from subsequent cohorts as most of these fish remain immature. The estimated A50 was generally between 6.0 and 7.0 for cohorts from the mid-1950s to the early 1980s, but declined dramatically thereafter to 5.1 in the 1988 cohort (Table 14, Fig. 21a). A50 has remained at this lower level, though the estimates for the 2003 and 2004 cohorts are improved - with A50 greater than 5.5 years. Given that the estimation is by cohort, estimates for the most recent cohorts may be revised slightly in future years as additional data is collected. Males show a similar trend in A50 over time (data not shown), but tend to mature about one year earlier than females.
Annual estimates of the proportion mature at age are shown in Table 15; these were obtained from the cohort model parameter estimates in Table 14. The estimates of proportion mature for ages 4-7 show a similar increasing trend (i.e., increasing proportions of mature fish at young ages) through the late 1970s and 1980s, particularly for ages 5, 6, and 7 (Fig. 21b). The current proportion mature at age remains high; however, the effect of increased A50 for the 2003 and 2004 cohorts, which equates to reduced proportion mature at age, is evident.

The time series of maturities for Subdiv. 3Ps cod shows a long-term trend as well as considerable annual variability. Such variations can have substantial effects on estimation of spawner biomass. Further, the age composition of the spawning biomass may have important consequences in terms of producing recruits (see Brattey et al. 2008).

Cod in Subdiv. 3Ps appear to spawn over a significant portion of the year and at many locations within the stock area. Spawning is spatially widespread and is known to occur on Burgeo Bank, St. Pierre Bank, and the Halibut Channel area, as well as inshore in Hermitage Bay (3Psa), Fortune Bay (3Psb) and Placentia Bay (3Psc). Spawning in Placentia Bay has been studied more intensively than elsewhere in Subdiv. 3Ps (Bolon and Schneider 1999; Lawson and Rose 1999; Bradbury et al. 2000).

## COHORT ANALYSES

During the 2006 assessment of this stock, it was agreed that sequential population analyses of Subdiv. 3Ps cod should be discontinued, primarily due to inconsistent trends in the index data available (poor correlations within and between surveys), poor model fit (strong year-effects and poor precision in estimated parameters). (For additional discussion, refer to DFO $(2006,2007)$ as well as Brattey et al. 2007.) In addition, during assessment meetings concerns have been expressed regarding the accuracy of the total landings captured by the commercial catch data (e.g., DFO 2010). In the 2007 assessment of this stock, Brattey et al. (2008) provided estimates of instantaneous rates of total mortality ( $Z$ ) for 1997 to 2007 as computed directly from the combined DFO RV survey. A debate on smoothing these annual estimates of total mortality during the winter 2009 zonal assessment meeting lead to the exploration of cohort modeling of the survey data to provide structure to the smoothing. Consequently, a survey-based (SURBA) model based upon the work of Cook (1997) was implemented and provides estimates of total mortality, relative recruitment strength, and relative estimates of total and spawning biomass from the DFO RV survey (see Cadigan 2010).

The age-disaggregated cohort model assumes that total mortality experienced by the population can be separated into vectors of age effects $s_{a}$ and year effects $f_{y}$ (such that $Z_{a, y}=s_{a} \times f_{y}$ ). Estimation (lognormal) minimizes the difference between the predicted and observed survey index over all ages and years, with penalties applied to impose a degree of smoothing on the estimated age and year effects. However, the model was speculative in that it could not reliably estimate survey catchability and this is fixed at scenario values. Detailed model specification, sensitivities of results to modeling assumptions, and estimation procedures applied during both the zonal and regional assessment meetings of 2009 are documented in Cadigan (2010). PROC NLMIXED in SAS/STAT ${ }^{\text {TM }}$ software is used to estimate parameter values and associated uncertainty. Data for ages 1-12 from the DFO RV expanded index were used, including an adjustment for the 1983 to 1996 survey indices to account for the inshore area that was not sampled in these years. However, data for ages 1 and 2 over 1983 to 1995 are zero-weighted in estimation, due to concerns of potential biases in RV data conversion of these age groups. (This conversion accounts for a change in the trawl gear after the 1995 survey.)
An updated run of the previous assessment model formulation was presented. Survey selectivity is assumed to be constant for ages $4+$, that is, selectivity is "flat-topped". An alternate assumption about selectivity "domed" was explored in previous years. It has been argued that best-practice is to assume flat-topped selectivity (Northeast Fisheries Science Center 2008) unless there is evidence otherwise. The age effects estimated in deriving a recruitment index from the age $1-4$ survey data (details in next section) were used to provide some objectivity in the survey catchabilities supplied to the model. Model diagnostics are similar to results obtained during the previous assessment. Estimated survey spawning stock biomass (SSB) relative to the biomass limit reference point ( $\mathrm{B}_{\mathrm{lim}}$ ) from the updated run is consistent with those from the previous assessment, and indicate a considerable decline in survey SSB over 2003 to 2009 (Fig. 22a). The estimate of 2010 and 2011 survey SSB in the update run indicates some increase compared to the 2009 estimate, with the median 2011 SSB estimated to be 1.34 times the limit reference point (LRP; Fig. 22a; also see Appendix 1).

Estimates of total mortality (Fig. 22b) show consistent increase over 1997 to 2011, and mortality over 2006 to 2010 (ages $5-10$ ) averaged 0.68 ( $49 \%$ mortality). This high level of mortality is a concern. Total mortality rates reflect mortality due to all causes, including fishing. Estimated recruitment shows that the 2006 year-class is much stronger than several prior year-classes (Fig. 22c) and that the 20072009 year-classes all appear to be near the time-series average. Model diagnostics show evidence of the year-effects described in the survey results section, some of which are large in magnitude.

Otherwise, there are no indications of systematic model fit issues (Fig. 23). Detailed output of estimation and model results is provided in Appendix 1.
Survey population estimates were projected to 2014 assuming total mortality rates were similar to current values (i.e., within $+/-20 \%$ ). Recruitment was assumed to be the geometric mean of the age 1 estimates over 2008 to 2010, and weights at age were assumed to equal the average of those over 2008-10. The proportions mature at age were projected forward from the cohort-specific model estimates. Five projection scenarios were conducted, using multipliers of $0.8,0.91 .0,1.1$, and 1.2 current $Z$, with a constant mortality rate assumed for each year projected. The one-year projection results indicated that survey SSB will increase if total mortality rates are similar to current values (i.e., within $\pm 20 \%$ ), and that the probability of being below the LRP in 2012 is low ( 0.02 to 0.09 ). This increase is driven by the continued recruitment of the 2006 year-class into the spawning biomass. By 2014, however, there are projected declines in both total biomass and spawning biomass if total mortality is similar to current values. In 2014 the probability of being below the LRP ranges from 0.03 (if mortality is $20 \%$ lower than current) to 0.56 (mortality $20 \%$ higher).

## CONCLUSIONS AND ADVICE

The assessment concluded from tagging data and ancillary information that the complex of stock components exploited by fisheries in Subdiv. 3Ps does not comprise a single stock for which population biomass and abundance can be estimated from existing information. Therefore the impacts of fishing at specific TAC levels on all stock components could not be quantified. However, the DFO RV survey covers most of the stock, and survey trends broadly reflect stock trends. Indices based on the RV survey have been used to assess current status of the stock relative to historic observations and to evaluate growth and sustainability of the stock.

A limit reference point ( $B_{\text {Recovery }}$ ) was identified for this stock during the 2004 assessment (DFO 2004). It is defined as the lowest observed SSB from which there has been a sustained recovery; the 1994 value of SSB has been identified as the LRP.

SSB decreased over the 2004 to 2009 period. Median SSB was estimated to be below the LRP in 2008 and 2009. The SSB in 2011 is estimated to be above the LRP, with a low probability of being below the LRP (0.08). A one year projection to 2012 using the cohort model indicated that survey SSB will continue to increase if total mortality is similar to current values (i.e., within $\pm 20 \%$ ). This increase is due to the recruitment of the relatively strong 2006 year class to the spawner biomass. The projection also indicated that the probability of being below the LRP in 2012 is low ( 0.02 to 0.09 ). A three year projection to 2014 indicates subsequent declines in both total biomass and spawning biomass if total mortality is similar to current values (i.e., within $\pm 20 \%$ ). In 2014 the probability of being below the LRP ranges from 0.03 to 0.56 .
The 2006 cohort is estimated to be relatively strong and is expected to recruit to the 2011 fishery. The 2007 to 2009 cohorts are estimated to be near the 1982 to 2010 average.
Estimates of total mortality (ages 5-10) over 2006 to 2010 averaged 0.68 ( $49 \%$ mortality). This high level of mortality is a concern. Total mortality rates reflect mortality due to all causes, including fishing.
Exploitation rates for 2010 based on tagged cod released in Placentia Bay ranged from 28-33\% for large cod ( $>65 \mathrm{~cm}$ ) and 10-17\% for smaller cod ( $<65 \mathrm{~cm}$ ).
Gillnet catch rates from both sentinel surveys and logbooks for vessels <35 ft suggest stability. However, line-trawl catch rates from these sources indicate recent decline.

Overall, the findings of the current assessment are consistent with those of previous assessments. The Subdiv. 3Ps cod SSB at the beginning of 2011 was estimated to be above the LRP.

## OTHER CONSIDERATIONS

## MANAGEMENT CONSIDERATIONS

The implementation of trip limits, price differentials based on size, and individual quotas, are all potential incentives for discarding and high-grading of catches. Recent investigations into this problem have identified that high-grading has occurred, but the quantity has not been determined. Quantifying discards would improve the understanding of stock productivity. This is an unaccounted source of fishing mortality.

Management should recognize that cod which overwinter in Subdiv. 3Ps are also exploited in adjacent stock areas (Div. 3L and Subdiv. 3Pn). Hence management actions in these stock areas should consider potential impacts on Subdiv. 3Ps cod.

Recent results confirmed that closures to protect spawning or mixed-stock aggregations are appropriate.

Consequences of area/time closures should be carefully considered as these may result in higher exploitation rates on the components of the stock that remain open to fishing. The fishery should be managed such that catches are not concentrated in ways that result in high exploitation rates on any stock components.

Management should be aware of within-year variations in the individual weight of cod. Greatest yield can be gained when fish are in peak condition, typically in late fall/early winter, while minimizing the number of individuals removed from the stock.

The level of total removals is uncertain. In assessing stock status, it would be useful to better understand the accuracy of total removals, especially in the post-moratorium when commercial catches are more strictly monitored. Accurate estimates of recreational fishery landings are also required.

## TEMPERATURE

Oceanographic information collected during the spring DFO RV surveys indicated that near-bottom temperatures throughout Subdiv. 3Ps have warmed in both 2009 and 2010, increasing to above normal values. For example, the area of $<0^{\circ} \mathrm{C}$ water has decreased to about $10 \%$ of the survey area, compared to almost $30 \%$ in 2007 and 2008. Survey catches of cod are generally lower in years when there are relatively large incursions of cold/fresh water from the eastern Newfoundland shelf. The areal extent of bottom water with temperatures $>3^{\circ} \mathrm{C}$ has remained relatively constant at about $50 \%$ of the total Div. 3P area, although actual temperature measurements show considerable inter-annual variability. The current conditions are comparable to those of the late 1970s and early 1980s when the stock was more productive.

## SOURCES OF UNCERTAINTY

The level of total removals is uncertain. It is likely that historical landings have been biased both upwards (e.g., due to misreporting of catch by area and/or species) and downwards (e.g., due to discarding). In addition, commercial catch accounting procedures pre- and post-moratorium are radically different, with current measures likely to provide improved estimates of removals. In assessing stock status, it would be useful to better understand the accuracy of total removals, especially in the post-moratorium. Estimates of recreational fishery landings have not been available since 2006.
There is uncertainty regarding the origins of fish found in Subdiv. 3Ps at various times of the year. Tagging and telemetry experiments show that there is mixing with adjacent stocks (southern Div. 3L and Div. 3Pn4RS) and this may vary over time.

The DFO RV survey covers most of the stock, and survey trends broadly reflect stock trends. Any near-shore aggregations in April would not be measured by the DFO RV survey. The majority of the area shore-ward of the RV survey lies within inner and western Placentia Bay. There is no recent evidence that a large fraction of the stock is shore-ward of the RV survey in April.
There is evidence that the recruitment productivity of the stock has changed over time, and that the stock has been less productive since 1990 than in earlier periods. The causes for these changes are not well understood. Better understanding of this issue is required and could have important implications for any management targets and maximum sustainable yield (MSY) reference points. This reduction in recruitment productivity may be consistent with harvester perspective on the declining abundance of capelin in Subdiv.3Ps.

Comparison of sentinel catch rates and the DFO RV index at times show inconsistent agecompositions. This may be indicative of differences in cohort strength between stock components. For example, the sentinel gillnet data consistently measured the 1992 cohort as being an above average fraction of the annual catch. This cohort was also important to the commercial gillnet catch, but was not notable in the RV index. A similar phenomenon exists for the 2004 cohort (detected by sentinel line-trawl but not sentinel gillnet or RV index).

The geographical coverage of tagging since 2007 is very limited; during 2008 to 2010 cod have only been tagged in Placentia Bay. The lack of recent tagging in other areas adds uncertainty to our understanding of natural mortality rates, exploitation rates, stock structure, and movement patterns and how these influence survey and commercial catch rates in the recent period.

The relative efficiency of the survey trawl at capturing different age groups is uncertain. Differing patterns of catchability were explored in recent assessments and yielded similar outcome in terms of current status relative to the LRP. If the catchabilities differ from the assumed values, stock dynamics may differ from the results presented above.

Survey indices are at times influenced by "year-effects", an atypical survey result that can be caused by a number of factors (e.g., environmental conditions, movement, degree of aggregation, etc.) which may be unrelated to absolute stock size. In the 2009 DFO RV survey, the estimated abundance at ages 2-8 increased compared to these cohorts at ages 1-7 as measured in the 2008 survey. This is unusual and indicates that one (or possibly both) of the 2008 and 2009 surveys may be influenced by a year-effect. Year-effects are also evident in the 1995 and 1997 survey results.

The percentage of the catch from the $<35 \mathrm{ft}$ sector that is accounted for in the standardized logbook indices has declined over time and now represents only about $30 \%$ of the catch as compared to approximately $70 \%$ at the start of the time series in 1997. This likely affects the quality and comparability of this index over time.

Age at $50 \%$ maturity has been declining in recent years. The proportion of female cod maturing at younger ages has been higher for all cohorts subsequent to the 1986 cohort, resulting in a significant proportion of SSB made up of younger fish. Questions exist as to whether or not these small, young fish are effective spawners. Given the lack of definitive data regarding size and age effects on spawner quality for this stock, the current practice of equally weighting all components of SSB (regardless of size and age) continues to be employed. However, if young spawners contribute disproportionately less to recruitment than older fish, the current reproductive potential of the stock would be lower than expected and would be reduced in comparison to the pre-1986 SSB, which was comprised of older fish.

## ACKNOWLEDGMENTS

This assessment is supported by the extensive efforts by DFO personnel who participate in collection of data during annual research surveys or sampling of the Subdiv. 3Ps commercial cod fishery. Additionally, data processing by D. Pittman and the age reading efforts of W. Edison, G. Cossitt, and C. Hiscock are gratefully acknowledged. Comments from D. Ings improved the quality of this manuscript.

Table 7a. Mean annual weights-at-age (kg) calculated from lengths-at-age based on samples from commercial fisheries (including food fisheries and sentinel surveys where available) in Subdiv. 3Ps in 1959-2010. The weights-at-age from 1976 are extrapolated back to 1959.

| Year/Age | 3 | 4 | 5 | 6 | 7 | 8 | 9 | 10 | 11 | 12 | 13 | 14 |

Table 9. Cod abundance estimates (000's of fish) from DFO bottom-trawl research vessel surveys in NAFO Subdiv. 3Ps during 1997-2011. Shaded cells are model estimates. See Fig. 13 for location of strata. For 1983 to 1996 results see Brattey et al. (2007).

${ }^{1}$ These strata were added to the stratification scheme in 1994.
${ }^{2}$ Stratum 709 was redrawn in 1994 and includes stratum 710 from previous surveys. All sets in 710 prior to 1994 were recoded to 709.
${ }^{3}$ For index strata 0-300 fathoms in the offshore and includes estimates (shaded cells) for non-sampled strata .
${ }^{4}$ totals are for all strata fished.
${ }^{5}$ These strata were added to the stratification scheme in 1997.
${ }^{6}$ std's are for index strata and do not include estimates from non-sampled strata.

Table 10. Cod biomass estimates (t) from DFO research vessel bottom-trawl surveys in NAFO Subdiv. 3Ps during 1997-2011. Shaded cells are model estimates. See Fig. 13 for location of strata. For 1983 to 1996 results see Brattey et al. (2007).

[^1]Table 11a. Mean numbers per tow at age (1-15 only) in Campelen units for the Canadian research vessel bottom trawl survey of NAFO Subdiv. 3Ps. Data are adjusted for missing strata. Upper table includes all data from offshore index strata; lower table includes data from inshore and offshore strata (area covered since 1997 - refer to text for additional detail). The survey in 2006 was not completed and there were two surveys in 1993 (February and April).

| Year/Age | Offshore Only |  |  |  |  |  |  |  |  |  |  |  |  |  |  |  |

Table 11b. Mean numbers per tow at age in Campelen units for the Canadian research vessel bottom trawl survey of the eastern and western (Burgeo area) portions of NAFO Subdiv. 3Ps. Data are adjusted for missing strata. There were two surveys in 1993 (February and April) and the 2006 survey was not completed. Only ages 1-14 and data for 1993 onwards are shown.

Table 15. Estimated proportions mature for female cod from NAFO Subdiv. 3Ps from DFO surveys from 1978 to 2011, projected forward to 2014. Estimates were obtained from a probit model fitted by cohort to observed proportions mature at age (from "combined" survey area). Shaded cells are averages of the three closest cohorts; boxed cells are the average of estimates for the adjacent cohorts.

| Year/Age | Age 1 | Age 2 | Age 3 | Age 4 | Age 5 | Age 6 | Age 7 | Age 8 | Age 9 | Age 10 | Age 11 | Age 12 | Age 13 | Age 14 |

Figure 1. NAFO Subdiv. 3Ps management zone showing the economic zone around the French islands of St. Pierre and Miquelon (SPM, dashed line), the 100 m and 250 m depth contours (grey lines) and the boundaries of the statistical unit areas (solid lines).

Figure 2. NAFO Subdiv. 3Ps management zone showing the economic zone around the French islands of St. Pierre and Miquelon (SPM, dashed line), the 100 m and 250 m depth contours (grey lines) and the main fishing areas.

Figure 3a. Reported landings of cod by Canadian and non-Canadian vessels in NAFO Subdiv. 3Ps during 1959 to October 2011. The 2011 fishery was still in progress at the time of the October 2011 assessment.

Figure 3b. Reported landings of cod by fixed and mobile gears in NAFO Subdiv. 3Ps during 1959October 2011. The 2011 fishery was still in progress at the time of the October 2011 assessment.

Figure 4. Percent of total fixed gear landings by the four main fixed gears used in the cod fishery in NAFO Subdiv. 3Ps during 1975 to 2010. The fishery was under a moratorium during 1994-96 and values for those years are based on sentinel and by-catch landings of $<800 t$.

Figure 5. Annual reported landings of cod (upper panel) and percent of annual total (lower panel) by unit area from NAFO Subdiv. 3Ps during 1997-2010. Refer to Figure 1 for locations of unit areas.

Figure 6a. Catch at age (numbers of fish; in thousands) for the cod fishery in Subdiv. 3Ps during 2006 to 2010. Does not include recreational catches from 2007 onward (see text).

Figure 6b. Percent catch at age for Subdiv. 3Ps cod from 2006 to 2010.

Figure 6c. Standardized proportions at age of commercial catch at age in Subdiv. 3Ps. Catch proportions within each year were computed, and then standardized by subtracting the mean proportion and dividing by the standard deviation of the proportions across years. Symbol sizes are scaled and values greater than average are shown as grey circles, average values are shown as small dots, and less than average values are shown as black circles. Labels in the upper and right margins identify cohorts. Upper panel shows catches from 1977 to 2010; lower panel includes catch from post-moratorium period (1997-2010).

Figure 7. Catch numbers-at-age for the main gear types used in the Subdiv. 3Ps cod fishery during 2010.

Figure 8. Mean weights-at-age calculated from mean lengths-at-age (upper panel: ages 3-8; lower panel: ages 9-14) for the commercial catch of cod in Subdiv. 3Ps during 1977 to 2010.

Figure 9. Beginning of year mean weights-at-age (upper panel: ages 3-8; lower panel: ages 9-14) from the commercial catch of cod in Subdiv. 3Ps during 1977 to 2010.

Figure 10a. Standardized age-aggregated catch rate indices for gillnets (5.5" mesh) and line-trawls (with $95 \%$ CL) estimated using data from sentinel fishery fixed sites. Dashed horizontal lines indicate time-series average.

Figure 10b. Standardized proportions at age of sentinel catch rates at age in Subdiv. 3Ps. Annual proportions were computed, and then standardized by subtracting the mean proportion and dividing by the standard deviation of the proportions across years. Symbol sizes are scaled and values greater than average are shown as grey circles, average values are shown as small dots, and less than average values are shown as black circles. Labels in the upper and right margins identify cohorts.

Figure 11a. Location and boundaries of numbered management areas along the inshore of the south coast of Newfoundland (Subdiv. 3Ps) (29 = Placentia Bay East, $30=$ Head of Placentia Bay, $31=$ Placentia Bay West, $32=$ The Boot, $33=$ Fortune Bay, $34=$ Head of Fortune Bay, $35=$ Connaigre, $36=$ Hermitage Bay, 37 = Francois-Burgeo).

Figure 11b. Area-specific median annual catch rates of cod from gillnets (left panel, kg per net) and line-trawls (right panel, kg per 1,000 hooks) from science log-books for vessels <35 ft. Labels on x-axis are lobster fishing areas ordered from west to east (see key on far right). Values in parenthesis on x-axis are number of valid sets per site during the 2010 fishery.

Figure 11c. Standardized catch rates for gillnets and line-trawls from science log-books for vessels <35 ft. Horizontal dashed lines are time-series average; error bars are 95\% confidence intervals of the means. Catch rates are expressed in terms of weight (kg per net or kg per 1000 hooks).

Figure 12. Stratum area boundaries and area surveyed during the DFO research vessel (RV) bottom-trawl survey of Subdiv. 3Ps. Dashed line is the boundary of the French economic zone which is included in the surveyed area.

Figure 13. Number of research vessel survey sets completed during surveys of Subdiv. 3Ps, and the number of days required to complete these sets over 1983 to 2011. Survey coverage was expanded to present levels after 1997 (dashed vertical line).

Figure 14. Abundance (upper panel) and biomass (lower panel) indices for cod in Subdiv. 3Ps from DFO research vessel (RV) bottom trawl surveys of index strata during winter/spring from 1983 to 2011. Error bars show plus/minus one standard deviation. Open symbols show values for the augmented survey area that includes additional inshore strata added to the survey in 1997. Dashed horizontal lines are mean of the timeseries for all index strata.

Figure 15. Total abundance index for cod in various regions of Subdiv. 3Ps from DFO research vessel (RV) bottom trawl surveys during winter/spring from 1997 to 2011. The 2006 survey was not completed. The Campelen trawl was used in all surveys.

Figure 16c. Age dis-aggregated distribution of cod catches (nos. per tow, ages 5-8) from the April 2011 DFO research vessel (RV) surveys of Subdiv. 3Ps. Bubble size is proportional to numbers caught.

$\begin{array}{ll}- & 1 \\ - & 10 \\ - & 50 \\ + & 225 \\ + & 0\end{array}$

Figure 16d. Age disaggregated distribution of cod catches (nos. per tow, ages 9-12) from the DFO research vessel (RV) survey of Subdiv. 3Ps during April 2011. Bubble size is proportional to numbers caught.

Figure 17. Standardized age-disaggregated catch rates from the spring bottom trawl survey of Subdiv. 3Ps. Catch rates (mean nos per tow) were converted to proportions within each year. Values were standardized by subtracting the mean proportion and dividing by the standard deviation of the proportions computed across years. Symbol sizes are scaled and values greater than average are shown as grey circles, average values are shown as small dots, and less than average values are shown as black circles. Labels in the upper and right margins identify cohorts. Left panel includes the 1997-2011 "All Strata <300 fm" data, and panel at right includes data which comprise the "Offshore" index (1983-2011).

Figure 18a. Mean length at ages 3-9 of cod in Subdiv. 3Ps during 1983 to 2011 from sampling during DFO bottom-trawl surveys in winter-spring.

Figure 18b. Average proportion deviation from mean length at age for ages 3-9 from DFO bottom-trawl surveys from 1983-2011.

Figure 18c. Least squares means (+ SE) of the effect of year on the residuals from a model of the age effect on length increment for ages 3-9 from DFO bottom-trawl surveys from 1983 to 2011.

Figure 19a. Mean round weight-at-age (kg) of cod sampled during DFO bottom-trawl surveys in Subdiv. 3Ps in winter-spring 1983-2011.

Figure 19b. Average proportion deviation from mean weight at age for ages 3-9 from DFO RV bottomtrawl surveys from 1983 to 2011.

Figure 20. Relative condition indices for Subdiv. 3Ps cod from spring surveys over 1993 to 2011. Upper panel is relative gutted condition index; lower panel relative liver condition index.

Figure 21a. Age at 50\% maturity by cohort (1954 to 2006, excluding 1963) for female cod sampled during DFO research vessel bottom-trawl surveys of Subdiv. 3Ps. Error bars are 95\% fiducial limits.

Figure 21b. Estimated proportions mature at ages 4-7 for female cod sampled during DFO research vessel bottom-trawl surveys in Subdiv. 3Ps (data from all strata surveyed).

Figure 22a. Estimates of spawning stock biomass (SSB) relative to Blim from SURBA cohort analysis model (i.e., estimates are divided by 1994 SSB).

Figure 22b. Estimates of total mortality (Z) from a SURBA cohort analysis model, averaged over ages 5-10.

Figure 22c. Estimates of age 1 recruitment from SURBA cohort analysis model.

Figure 23. Standardized residuals from SURBA cohort analysis. Panels show residuals plotted year, cohort, age, and expected value, respectively.

[^0]:    ${ }^{1}$ Provisional catches
    ${ }^{2}$ Includes recreational fishery and sentinel fishery.
    ${ }^{3}$ Since 2000, TAC's have been established for the period 1 April to 31 March rather than by calender year.
    ${ }^{4}$ Does not include estimates of recreational catch.

[^1]:    ' These strata were added to the stratification scheme in 1994
    < Strata 709 was redrawn in 1994 and includes the area covered by strata 710 previously. All sets done in 710 prior to 1994 recoded to 709 .
    ${ }^{\circ}$ For index strata 0-300 fathoms in the offshore and includes esitmates (shaded cells) for non-sampled strata .
    ${ }^{4}$ totals are for all strata fished.

    - These strata were added to the stratification scheme in 1997.
    ${ }^{u}$ std's are for index strata and do not include estimates from non-sampled strata.
