#### ABSTRACT

Vreeling, M.C., L. Hop Wo, A.P. Gould, W. Luedke, S.R. Heizer and T.D. Beacham. 1987. Biochemical Genetic Stock Identification of Chum Salmon in Southern B.C., 1986. Can. Data Rep. Fish. Aquat. Sci. No. 634: 19p.

Genetic variability among chum salmon stocks were used to estimate stock composition in both commercial and test fisheries in Southern British Columbia.

North and Central Coast and Queen Charlotte Island chum stocks comprised the main component in the northwest coast Vancouver Island troll fishery. The dominant stock in the Johnstone Strait fishery was the chum salmon of Johnstone and Georgia Strait origin. Georgia Strait chum salmon was the dominant run migrating through the Mid Vancouver fishery. Fraser River, Georgia Strait, West Coast Vancouver Island and U.S. stocks were mixed in the San Juan fishery. While West Coast Vancouver Island chum salmon the main component in the Nitinat fishery.

With the ability to identify these stocks, managers are able to structure new fisheries to minimize interception of non-target stocks as well as increase flexibility in fishery management.

Key words: chum salmon, genetic stock identification, fishery management.

#### RESUME

Vreeling, M.C., L. Hop Wo, A.P. Gould, W. Luedke, S.R. Heizer and T.D. Beacham. 1987. Biochemical Genetic Stock Identification of Chum Salmon in Southern B.C., 1986. Can. Data Rep. Fish. Aquat. Sci. No. 634: 19p.

Les auteurs ont utilisé les différences génétiques entre les stocks de saumon kéta pour estimer la composition des prises de pêches commerciales et d'essai effectuées dans le sud de la Colombie-Britannique. Les stocks de saumon kéta des parties nord et centre de la côte ainsi que de l'île de la Reine-Charlotte constituent la majorité des prises de la pêche à la traîne effectuée au large de la côte nord-ouest de l'île Vancouver. Les prises de la pêche du détroit Johnstone étaient surtout composées de saumons kétas provenant de ce détroit et du détroit de Géorgie. Les saumons kétas du détroit de Géorgie constituaient le principal groupe en migration exploité par la pêche de la partie centrale de l'île Vancouver. Les prises de la pêche de San Juan étaient constituées de poissons des stocks du fleuve Fraser, du détroit de Géorgie, de la côte ouest de l'île Vancouver et des Etats-Unis. Les saumons kétas de la côte ouest de l'île Vancouver dominaient les prises de la pêche de Nitinat.

Disposant de moyens d'identifier ces stocks, les gestionnaires peuvent structurer les nouvelles pêches de façon à minimiser l'interception des stocks non visés et à accroître la souplesse de la gestion des pêches.

## INTRODUCTION

Chum salmon returning to spawn in rivers tributary to Johnstone and Georgia Straits migrate primarily from the north through Johnstone Strait (Anderson and Beacham 1983), although in some years there can be a component of the run returning from the south through Juan de Fuca Strait (Beacham et al. 1987). The identification of the origins of chum salmon in these fisheries has become an increasing problem for management. In response to this problem a genetic method of stock identification (electrophoresis) has been employed since 1981 (Beacham et al. 1985). Domestically, this method has provided managers with the opportunities to assess the need to structure new fisheries to minimize interception of non-target stocks as well as to increase flexibility in fishery management. Internationally, stock identification results are used in identifying catch by country of origin and hence are used in implementing the terms of the Pacific Salmon Treaty between Canada and the U.S.

The largest mixed stock fishery in British Columbia occurs in Johnstone Strait. Different methods of stock identification have been examined for chum salmon. External tagging was an early method of stock identification which provided an understanding of general stock migration patterns (Pritchard 1929, 1931; Chatwin 1953; Manzer 1954; Anderson and Beacham 1983). It could not, however, provide timely in-season estimates of stock composition.

Variation in scale characters have been used in stock identification of chum salmon (Tanaka et al. 1969; Kovtun 1983; Nikolayeva and Semenets 1983). Meristic and morphometric studies were also conducted with only limited success (Beacham et al. 1983). None of these methods provides the ability to estimate stock composition during the fishery season.

Measuring genetically determined variations in protein structure in chum salmon stocks has shown promise for reliable estimates of stock composition (Wishard 1980; Okazaki 1981; Beacham et al 1985). In British Columbia initial surveys for biochemical genetic variation in chum salmon began in 1981 with the objective of providing managers with the ability to identify Fraser River chum salmon in a mixed stock fishery. Since 1981 additional baseline sampling has provided separation of other major chum stock areas.

Currently genetic stock identification (GSI) has provided managers of chum fisheries with the ability to discriminate between chum stocks from six major regions: (1) Queen Charlotte Islands; (2) North and Central coast; (3) West Coast of Vancouver Island; (4) Fraser River; (5) Johnstone and Georgia Strait area; (6) Washington State (U.S.A.) (Beacham et al. 1987). This report details the methods and results of stock identification for chum salmon in southern British Columbia fisheries using electrophoretic GSI for the 1986 season.

## METHOD

### (1) Collection

Collection of GSI samples occurred in the following fishing areas: Northwest coast of Vancouver Island (Area 111 & 127); Johnstone Strait (Area 12); Mid Vancouver Island (Area 14); San Juan (Area 20); Nitinat (Area 21); (Fig. 1). Samples were taken in order to determine the stock composition in these mixed fisheries.

In general, 150 chum salmon were sampled per week or, in the case of commercial fisheries, per fishing period. Tissue samples of heart, liver and muscle were collected within 24 hours of catch, frozen, and sent, packed with dry ice for electrohphoretic analysis. Processing was done by a consultant using the horizontal starch gel technique described by Utter et al. (1974).

Chum samples from the troll fishery off the northwest coast of Vancouver Island were randomly selected from day trollers returning to Winter Harbour. Variability in the number of chum salmon landed daily limited the consistency in sampling effort. A sample of insignificant size was obtained in Area 111 during July. Sampling commenced in Area 127 on June 2 and ended on August 4.

Samples from the Johnstone Strait fishery (Area 12) were collected by a chartered test fishing seine vessel at predetermined sites (Fig. 2). Each year test fishing vessels are chartered for stock assessment during which time electrophoretic samples are collected. Test fishing in the Hanson Island region commenced early September and a second test vessel commenced three weeks later in the Cracroft Point - Robson Bight region. Traditionally only the Hanson Island - Double Bay region was sampled. The second vessel was added to confirm existing stocks as well as provide an independent estimate of stock abundance. Test fishing continued in both regions till early November.

The sampling in the Mid Vancouver Island (Area 14) commercial fishery commenced on October 5 and continued for 5 weeks until November 3. Commercial fish packing vessels were boarded weekly in Comox Bay and Deep Bay to obtain randomly selected samples.

A D.F.O. test fishing vessel was chartered by D.F.O. to collect samples in the San Juan (Area 20) region. Sampling on a weekly basis began September 23 and was concluded on October 31. Sample sites were predetermined and chosen based on abundance (Fig. 3). Sampling was designed to avoid targeting on local stocks. Samples of approximately 150 fish were collected over a 3-5 day period stratified between the 6 different fishing sites each day.

In the Nitinat region (Area 21) samples were collected from fish plants in Ucluelet rather than on the fishing grounds as fish were more accessible in processing plants. Three samples from the commercial fishery were collected, one each week, beginning in September. Two additional samples were collected from the area test fishing vessel beginning the 4th week of September.

(2) Analysis -

After the electrophoretic analysis had been completed by the consultant, stock composition in the test fisheries was estimated by the method of Fournier et al. (1984), using the genotypic frequencies for the baseline stocks as outlined by Beacham et al. (1987). The allocation method was similar to that outlined by Beacham et al. (1987). Standard deviations of the estimates were determined by bootstrap simulations where 50 new mixtures were constructed by sampling the original mixture with replacement. Stock composition was then estimated for each of these new mixtures and standard deviations derived from the 50 estimates.

#### RESULTS

Regional differentiation of allelic frequencies for chum salmon was observed and are presented in Tables 1 through 5. The most common allele at a locus was designated 100 and other alleles were assigned numbers according to the mobility of their homomeric protein products.

The results of biochemical genetic variants indicated that variation among regions is substantially greater than among stocks within regions. This enables managers to provide in-season and post-season estimates of stock composition for use in fisheries management.

North Coast, Central Coast and Queen Charlotte Island chum were the main component in the troll fishery off the northwest coast of Vancouver Island. Composition of Fraser River, Georgia Strait and U.S. chum were insignificant in the troll fishery (Table 6).

The results obtained from both test vessels (Hanson Island, Cracroft Point - Robson Bight) located in the Johnstone Strait were consistent with each other. An estimated peak of Fraser River chum salmon abundance in Johnstone Strait was during the week of September 27. Johnstone and Georgia Strait chum peaked in the fishery two weeks later during October 11 to October 18. An insignificant component of U.S. fish were recorded (Table 7).

Johnstone and Georgia Strait chum salmon were the main component in the Mid Vancouver Island fishery (Table 8). The U.S. return peaked in the Mid Vancouver Island fishery during the week of October 11 while the Fraser River run peaked during the week of October 25.

Sampling in the San Juan fishery indicated substantial mixing of Fraser River, Georgia Strait, West Coast Vancouver Island and U.S. chum salmon (Table 9). Georgia Strait chums were, however, the major stock component.

West Coast Vancouver Island chum salmon were the dominant stock in the Nitinat fishery. Fraser River, Georgia Strait, and U.S. chums comprised an insignificant component in the Nitinat area (Table 10).

The stock composition expressed as percentages by major areas of concern (Fraser River; Johnstone and Georgia Strait; United States; West Coast Vancouver Island; North and Central Coast and Queen Charlotte Islands) are depicted in Tables 6 through 10.

#### ACKNOWLEDGEMENTS

The extensive field sampling necessary for this program would not have been accomplished without the help of many people. Among those involved were Al Dunlop, Jim Lettic, Jim Mitchell, Matt Palmer, Dave Ritchie, Bob Sewid, James Sewid, Oswald Sewid, Arnie Sorenson, "Moon" Stauffer, Alf Stefanson and Ivan Winthrop. We would also wish to thank Kingfisher Ent., in Parksville, Ocean Fish in Vancouver, Seafood Products in Port Hardy, Sliammon Hatcheries in Powell River and Trans Pacific Fish in Ucluelet for their cooperation in obtaining biological samples. The electrophoretic analysis of stocks was conducted by Helix Biotech Ltd. of Richmond, British Columbia, under contract to the Department of Fisheries and Oceans.
