Canadian Manuscript Report of Fisheries and Aquatic Sciences

Manuscript reports contain scientific and technical information that contributes to existing knowledge but which deals with national or regional problems. Distribution is restricted to institutions or individuals located in particular regions of Canada. However, no restriction is placed on subject matter, and the series reflects the broad interests and policies of the Department of Fisheries and Oceans, namely, fisheries and aquatic sciences.

Manuscript reports may be cited as full publications. The correct citation appears above the abstract of each report. Each report is abstracted in *Aquatic Sciences and Fisheries Abstracts* and indexed in the Department's annual index to scientific and technical publications.

Numbers 1-900 in this series were issued as Manuscript Reports (Biological Series) of the Biological Board of Canada, and subsequent to 1937 when the name of the Board was changed by Act of Parliament, as Manuscript Reports (Biological Series) of the Fisheries Research Board of Canada. Numbers 901-1425 were issued as Manuscript Reports of the Fisheries Research Board of Canada. Numbers 1426-1550 were issued as Department of Fisheries and the Environment, Fisheries and Marine Service Manuscript Reports. The current series name was changed with report number 1551.

Manuscript reports are produced regionally but are numbered nationally. Requests for individual reports will be filled by the issuing establishment listed on the front cover and title page. Out-of-stock reports will be supplied for a fee by commercial agents.

Rapport manuscrit canadien des sciences halieutiques et aquatiques

Les rapports manuscrits contiennent des renseignements scientifiques et techniques qui constituent une contribution aux connaissances actuelles, mais qui traitent de problèmes nationaux ou régionaux. La distribution en est limitée aux organismes et aux personnes de régions particulières du Canada. Il n'y a aucune restriction quant au sujet; de fait, la série reflète la vaste gamme des intérêts et des politiques du ministère des Pêches et des Océans, c'est-à-dire les sciences halieutiques et aquatiques.

Les rapports manuscrits peuvent être cités comme des publications complètes. Le titre exact paraît au-dessus du résumé de chaque rapport. Les rapports manuscrits sont résumés dans la revue *Résumés des sciences aquatiques et halieutiques*, et ils sont classés dans l'index annuel des publications scientifiques et techniques du Ministère.

Les numéros 1 à 900 de cette série ont été publiés à titre de manuscrits (série biologique) de l'Office de biologie du Canada, et après le changement de la désignation de cet organisme par décret du Parlement, en 1937, ont été classés comme manuscrits (série biologique) de l'Office des recherches sur les pêcheries du Canada. Les numéros 901 à 1425 ont été publiés à titre de rapports manuscrits de l'Office des recherches sur les pêcheries du Canada. Les numéros 1426 à 1550 sont parus à titre de rapports manuscrits du Service des pêches et de la mer, ministère des Pêches et de l'Environnement. Le nom actuel de la série a été établi lors de la parution du numéro 1551.

Les rapports manuscrits sont produits à l'échelon régional, mais numérotés à l'échelon national. Les demandes de rapports seront satisfaites par l'établissement auteur dont le nom figure sur la couverture et la page du titre. Les rapports épuisés seront fournis contre rétribution par des agents commerciaux.

ABSTRACT

Schubert, N.D., G.E. Rosberg, R.J. Cook and G.M.W. Cronkite. 1985. A coded wire tag assessment of Birkenhead River coho salmon: 1982 tag application and 1984 spawner enumeration. Can. MS Rep. Fish. Aquat. Sci. 1816: 55 p.

Coho juveniles in the Birkenhead River were captured and coded wire tagged during the fall of 1982. A total of 43,566 age 0+ and 3,432 age 1+ coho were released with codes 02 22 09 and 02 23 26 respectively. Mean size of tagged age 0+ coho was 55.8 mm and 2.0 g; tagged age 1+ coho averaged 84.7 mm and 7.0 g.

The subsequent spawner escapement was estimated at 11,524, of which an estimated 327 and 31 were tagged with codes 02 22 09 and 02 23 26 respectively. Estimated survival to escapement was 0.8% and 1.0% for the two respective tag codes.

Key words: Birkenhead River, coho salmon, coded wire tagging, escapement, survival.

RÉSUMÉ

Schubert, N.D., G.E. Rosberg, R.J. Cook and G.M.W. Cronkite. 1985. A coded wire tag assessment of Birkenhead River coho salmon: 1982 tag application and 1984 spawner enumeration. Can. MS Rep. Fish. Aquat. Sci. 1816: 55 p.

À l'automne 1982, on a capturé des saumons cohos juvéniles dans la rivière Birkenhead, auxquels on a posé des étiquettes métalliques codées. Au total, 43,566 cohos de 0+ an et 3,432 poissons de 1+ an portant respectivement les codes 02 22 09 et 02 23 26 ont été relâchés. La taille moyenne des cohos de 0+ an étiquetés s'élevait à 55.8 mm et 2.0 g tandis que ceux de 1+ an atteignaient en moyenne 84.7 mm et 7.0 g.

On a calculé que l'échappée ultérieure totalisait 11,524 poissons, dont environ 327 et 31 portaient respectivement les codes 02 22 09 et 02 23 26. La survie estimative jusqu'à l'échappée s'élevait respectivement à 0.8% et à 1.0% pour les deux séries de codes.

Mots-clés: rivière Birkenhead, saumon coho, étiquettes métalliques codées, échappée, survie.

INTRODUCTION

A coho salmon coded wire tagging (CWT) study was conducted during the autumn of 1982 in the Birkenhead River, a large tributary of the Harrison/ Lillooet River system located near Pemberton, B.C. (Fig. 1). This study was one of several recently initiated in the Fraser River system to determine, through the coast-wide mark recovery program, the exploitation rate, catch distribution and survival rate of specific coho stocks (Schubert 1982, 1984; Fedorenko and Cook 1982; Hutton *et al.* MS 1983; Schubert and Fedorenko 1985).

Birkenhead River coho were selected for study for two reasons. First, although the salmonid resource of the Birkenhead River system has been the subject of intensive investigation by both the International Pacific Salmon Fisheries Commission (IPSFC) and the Department of Fisheries and Oceans, comparatively little effort has been devoted to coho salmon. This study was designed, therefore, to document the life history characteristics, exploitation rate and harvest distribution of Birkenhead River coho salmon. Second, since Birkenhead River coho are a major Fraser River coho stock, with escapements during the 1970's averaging approximately 5% of the Fraser River system total, assessment of this stock received a high priority.

Birkenhead River coho juveniles were trapped and coded wire tagged during the autumn of 1982 and returning spawners were enumerated during the autumn and winter of 1984/5. This report describes the field techniques and documents the results of both the juvenile and adult components of the Birkenhead River CWT study. Detailed data presented here include juvenile catch by species, numbers of coho released with CWT's, size and age characteristics of coho juveniles and adults, estimates of total escapement and escapement by CWT code, and de-

scriptions of rearing and spawning distributions. A full analysis of exploitation rate, survival rate and harvest distribution will be published when catch data are finalized.

STUDY AREA DESCRIPTION

The Birkenhead River arises in the Coast Mountains near Sun God Mountain (2,280 m) and flows in a southerly direction for approximately 54 km before entering the upper end of Lillooet Lake, 1 km north of the upper Lillooet River confluence (Fig. 1). The river drains a mountainous, partially glaciated watershed of 596 km² and is among the largest tributaries of the Harrison/Lillooet system.

The Birkenhead River flows for much of its length through a narrow valley bounded by steep mountains. Tributary streams enter from steep side valleys and generally flow directly into the main river. As a result, salmonid habitat is largely confined to mainstem and side channel areas, to short seepage-fed flood plain tributaries and to the deltaic portions of larger tributaries. The river is passable to adult chinook salmon as far upstream as Taillefer Creek (34 km) (Koster MS 1976); however, a 2 m rock falls in a deep bedrock canyon located 27.5 km upstream from Lillooet Lake delineates the apparent upper limit of coho migration. Below the canyon, the river flows for 19.5 km through a narrow, flat bottomed valley and is characterized by long rapids and riffles, frequent deep pools and isolated braided areas. The river flows from the mountain valley onto the Lillooet River flood plain approximately 8 km upstream, then flows to the mouth in a slow moving, meandering channel parallel to the upper Lillooet River.

The Birkenhead River hydrograph reflects a dominant spring snow melt modified by fall and spring precipita-

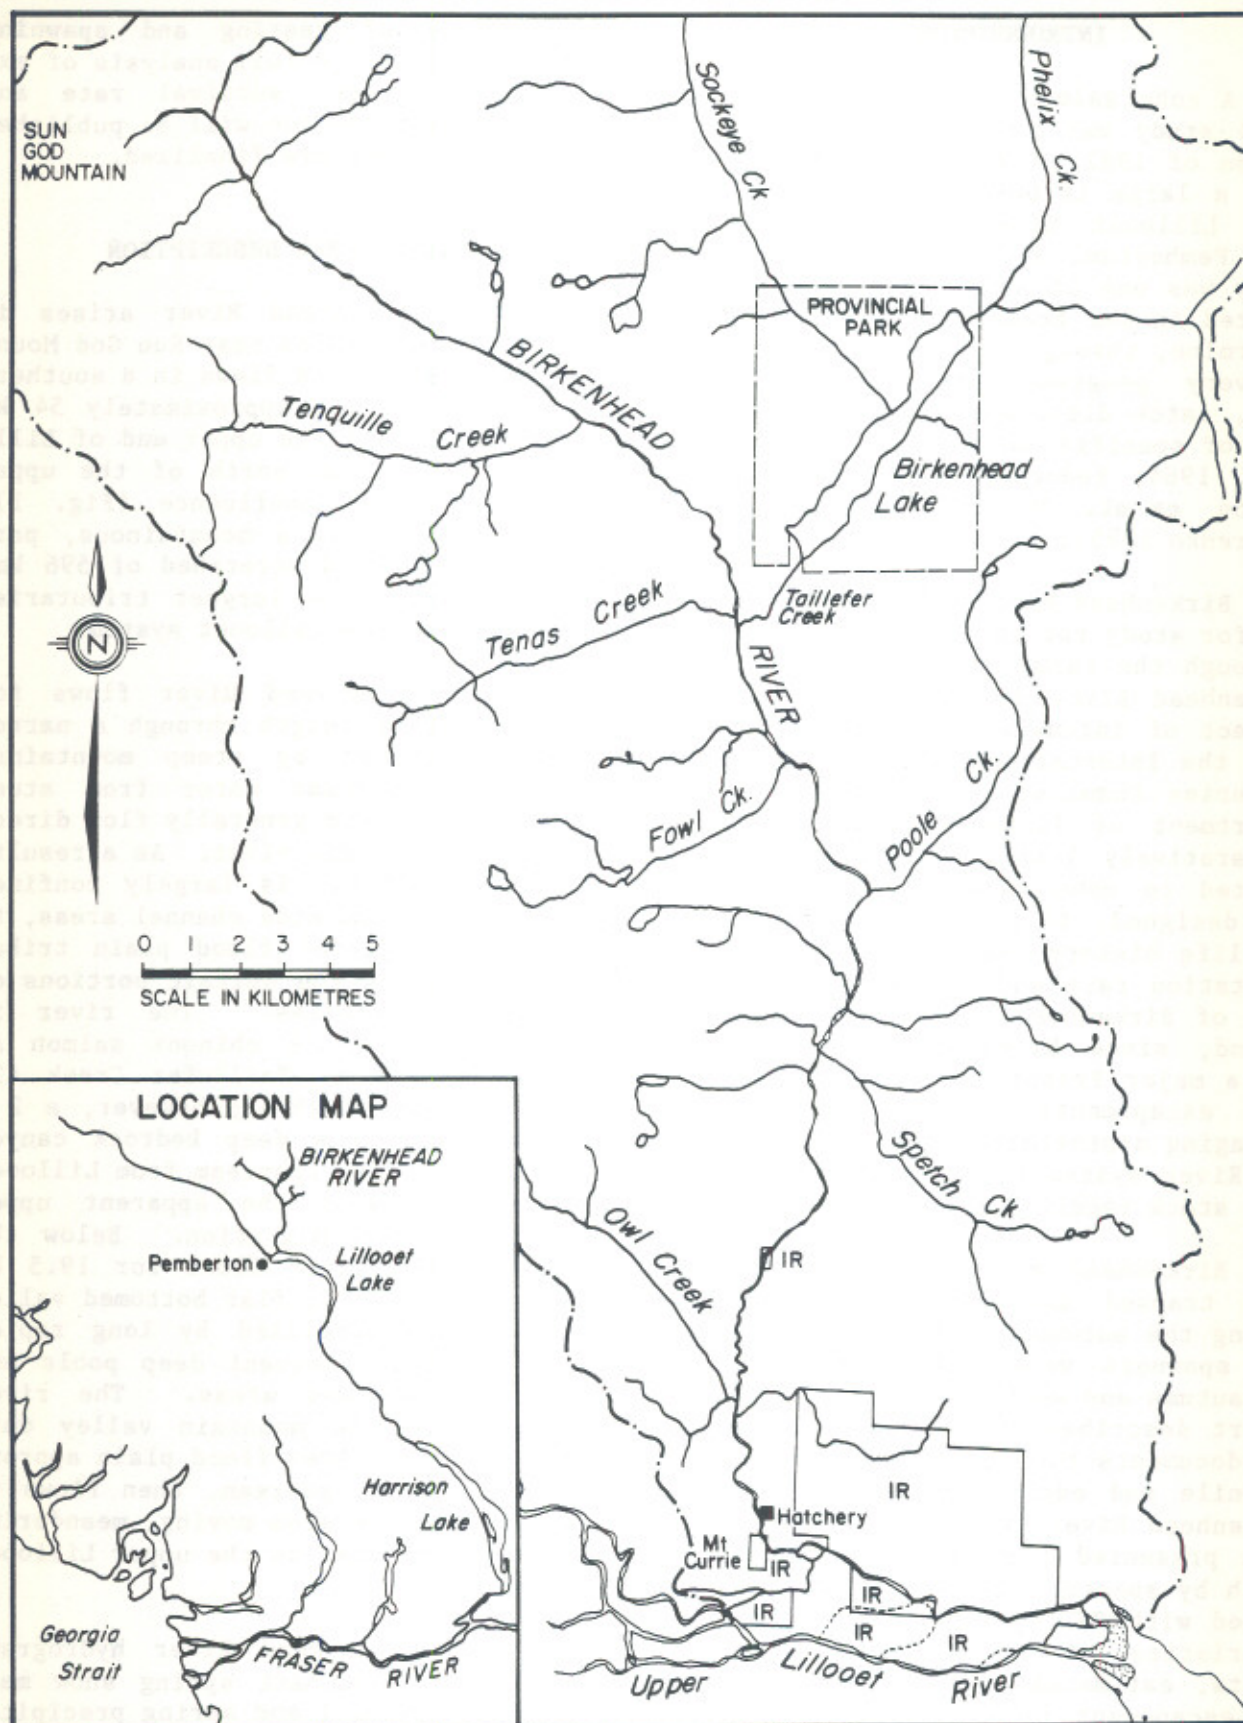

Figure 1 Map of Birkenhead River system and watershed

tion inputs (Fig. 2, Appendix 1). Daily discharges averaged 23.9 cubic meters per second (m^3/s) over a 26 year period of record ending in 1981. Maximum and minimum mean daily discharges generally occurred in June ($70.7 \text{ m}^3/\text{s}$) and March ($7.5 \text{ m}^3/\text{s}$) respectively.

Human settlement in the Birkenhead watershed is concentrated in the lower reaches where Indian reserves of the Mount Currie Band border the river (pop. 1,161; IANDC 1983). Agricultural activities have had the greatest impact on the Birkenhead River salmonid resource. In 1947, the lower river was diverted to the current channel from one which drained directly into the upper Lillooet River, approximately 4.5 km above Lillooet Lake. In 1949, the outlet of Lillooet Lake was dredged, lowering the lake level by 2 m and draining a large marsh on the upper Lillooet River delta. Since

that time, sections of the Birkenhead River and much of the lower 40 km of the upper Lillooet River have been dyked. Other human influences have been associated with the use of the valley as a transportation (railroad, highway) and hydroelectric transmission corridor. Rights-of-way are sprayed with herbicides and, as recently as 1972, train derailments have deposited deleterious materials into the river.

The Birkenhead River supports populations of sockeye, coho and chinook salmon (Appendix 2) as well as cutthroat trout, Dolly Varden char and whitefish. Sockeye are dominant, with an average escapement (1951-1984) of 69,000 and a maximum of 173,500 recorded in 1974. Coho escapements averaged 3,300 since 1951, with a maximum of 15,750 recorded in 1952. Chinook escapements averaged 700 since 1951, with a maximum of 3,500 recorded in 1957.

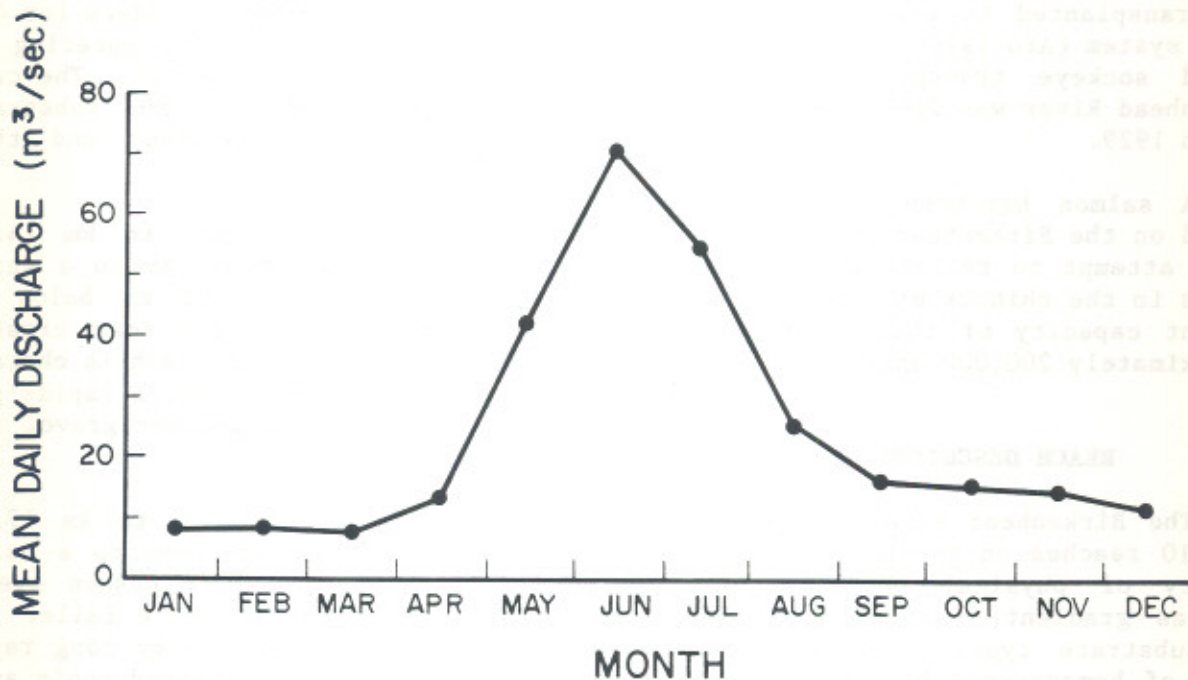

Figure 2 Mean daily discharge by month in the Birkenhead River near Mt. Currie, 1946-1971

The Birkenhead River system has been the subject of intensive fisheries activities since early in the century. The Department of Fisheries operated a salmon hatchery on the Birkenhead River near Owl Creek from 1905 until the hatchery program was abandoned in 1936. The facility, with a capacity of approximately 45 million eggs, was primarily for sockeye although up to 1.5 million coho, 150,000 chinook and 197,000 Kamloops trout eggs were taken in some years. The primary purpose of this facility was to augment natural salmon production in order to offset the effects of over fishing. The facility was also used to distribute Kamloops trout from Lloyd's Creek (Kamloops) to local lakes and streams and, during the period 1919 to 1931, the facility played a major role in attempts to reestablish sockeye production in systems impacted by the Hell's Gate slide. Birkenhead River sockeye were transplanted to the Eagle, Quesnel, Nechako and Stuart systems, and to the Skeena system to compensate for Skeena sockeye transplanted to the upper Fraser River system (Aro 1979). The only recorded sockeye transplant into the Birkenhead River was from Sweltzer River in 1929.

A salmon hatchery was reestablished on the Birkenhead River in 1977 in an attempt to reverse apparent declines in the chinook escapement. The current capacity of this facility is approximately 200,000 eggs.

REACH DESCRIPTIONS

The Birkenhead River was divided into 10 reaches on the basis of homogeneity of physical characteristics such as gradient, channel morphology and substrate type. Extensive sections of homogeneous habitat were divided into several reaches in order to more closely relate biological data to the sample sites. The reaches are described below and detailed in Fig. 3.

Unless otherwise noted, river distances are in kilometers upstream from Lillooet Lake. Local names for landmarks or creeks without official names are bracketed.

Reach 1 (mouth to km 7.4). Reach 1 is characterized by a meandering channel with a low gradient, a sand and mud substrate and extensive stream side vegetation. The Mount Currie Indian reserve borders both sides of the channel for virtually the entire reach.

Reach 2 (km 7.4 to km 9.7). Reach 2 is a transition area where the river flows from the mountain valley onto the Lillooet River flood plain. The reach, which extends from the road crossing immediately below the Birkenhead Hatchery downstream to the confluence of an unnamed tributary (Warbonnet Creek), is characterized by long riffles, isolated deep pools and a gravel substrate.

Warbonnet Creek meanders for 4 km across the flood plain, entering the Birkenhead River at km 7.4. The creek is characterized by a mud substrate, rooted aquatic vegetation and thick riparian growth.

Reach 3 (km 9.7 to km 14.7). Reach 3 extends upstream to a series of rapids located 0.5 km below the Mount Currie - Birken road crossing (Twin Bridges). The reach is characterized by a 2% gradient, a rapids/pool stream form and a boulder/gravel substrate.

Reach 4 (km 14.7 to km 17.5). Reach 4 extends upstream to a narrow gorge where the river passes over a series of small, passable falls. The reach is characterized by long rapids and riffles, deep isolated pools and a substrate of mixed gravel/cobble, with boulders present in the faster sections. Pools in this reach provided extensive adult coho holding habitat.

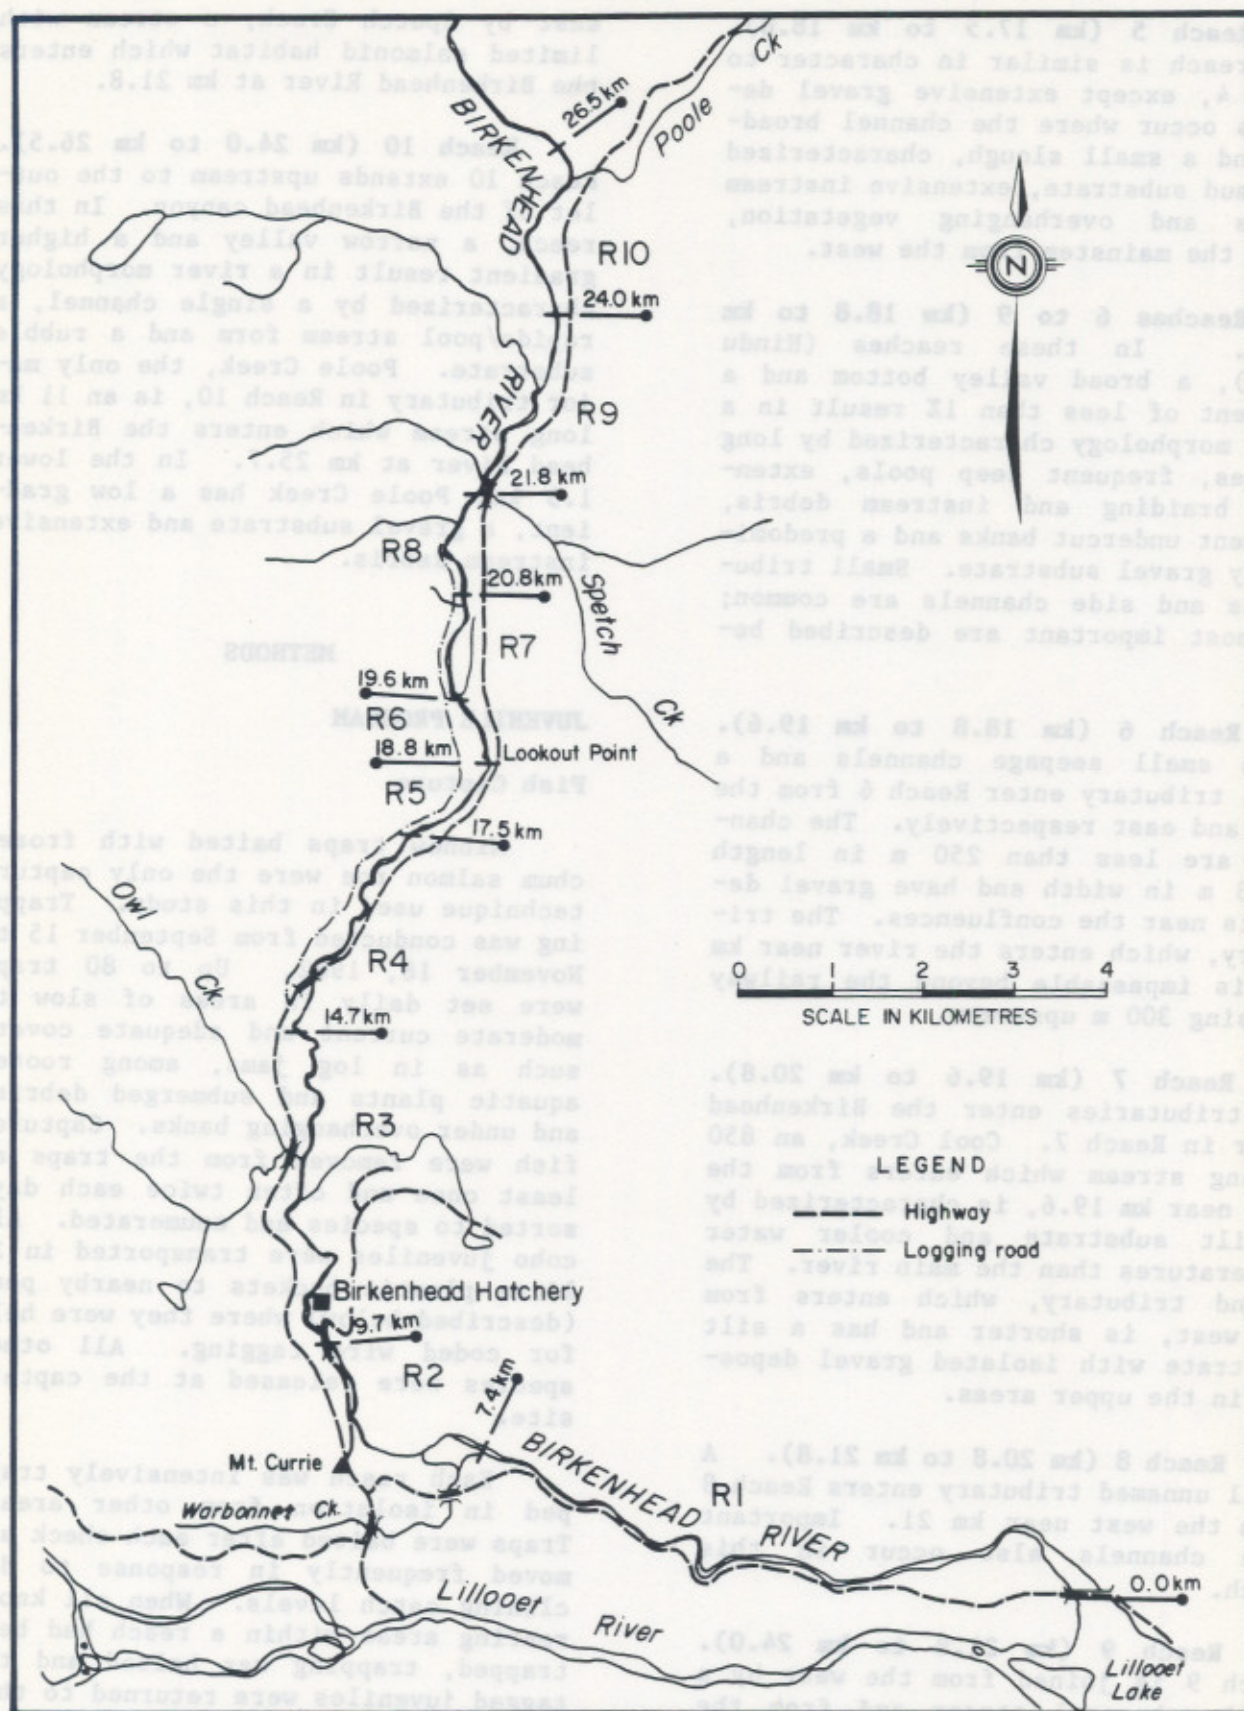

Figure 3 Study area location map, with reach delineations

Reach 5 (km 17.5 to km 18.8).

This reach is similar in character to Reach 4, except extensive gravel deposits occur where the channel broadens and a small slough, characterized by a mud substrate, extensive instream debris and overhanging vegetation, joins the mainstem from the west.

Reaches 6 to 9 (km 18.8 to km 24.0). In these reaches (Hindu Flats), a broad valley bottom and a gradient of less than 1% result in a river morphology characterized by long riffles, frequent deep pools, extensive braiding and instream debris, frequent undercut banks and a predominantly gravel substrate. Small tributaries and side channels are common; the most important are described below.

Reach 6 (km 18.8 to km 19.6).

Three small seepage channels and a small tributary enter Reach 6 from the west and east respectively. The channels are less than 250 m in length and 3 m in width and have gravel deposits near the confluences. The tributary, which enters the river near km 19, is impassable beyond the railway crossing 300 m upstream.

Reach 7 (km 19.6 to km 20.8).

Two tributaries enter the Birkenhead River in Reach 7. Cool Creek, an 850 m long stream which enters from the east near km 19.6, is characterized by a silt substrate and cooler water temperatures than the main river. The second tributary, which enters from the west, is shorter and has a silt substrate with isolated gravel deposits in the upper areas.

Reach 8 (km 20.8 to km 21.8).

A small unnamed tributary enters Reach 8 from the west near km 21. Important side channels also occur in this reach.

Reach 9 (km 21.8 to km 24.0).

Reach 9 is joined from the west by a small ephemeral stream and from the

east by Spetch Creek, a stream with limited salmonid habitat which enters the Birkenhead River at km 21.8.

Reach 10 (km 24.0 to km 26.5).

Reach 10 extends upstream to the outlet of the Birkenhead canyon. In this reach, a narrow valley and a higher gradient result in a river morphology characterized by a single channel, a rapids/pool stream form and a rubble substrate. Poole Creek, the only major tributary in Reach 10, is an 11 km long stream which enters the Birkenhead River at km 25.7. In the lower 1.5 km, Poole Creek has a low gradient, a gravel substrate and extensive instream debris.

METHODS

JUVENILE PROGRAM

Fish Capture

Minnow traps baited with frozen chum salmon roe were the only capture technique used in this study. Trapping was conducted from September 15 to November 18, 1982. Up to 80 traps were set daily in areas of slow to moderate current and adequate cover, such as in log jams, among rooted aquatic plants and submerged debris, and under overhanging banks. Captured fish were removed from the traps at least once and often twice each day, sorted to species and enumerated. All coho juveniles were transported in 23 litre plastic buckets to nearby pens (described below) where they were held for coded wire tagging. All other species were released at the capture site.

Each reach was intensively trapped in isolation from other areas. Traps were baited after each check and moved frequently in response to declining catch levels. When all known rearing areas within a reach had been trapped, trapping was halted and the tagged juveniles were returned to that

area.

Juvenile Coho Holding

Prior to tagging, all coho juveniles were held in instream pens constructed from 0.9 m x 1.8 m plastic (ABS) pipe frames and 4.8 mm mesh marquisette netting. Snap-on plastic covers provided shade and protection from avian predators. Floats (boat-bumpers) were attached to the ABS frame uprights to permit the pens to float during high discharges. Holding sites in each discrete trapping area were selected on the basis of four criteria: protection from turbulence; proximity to trapping areas; the presence of an adequate supply of clean, oxygenated water at low flows; and ease of access. When holding areas were unavailable at the capture site, juveniles were transported to the nearest available holding area.

Daily catches were graded by size into separate pens in order to minimize cannibalism. Pen loading densities were loosely based on those recommended by McNeil and Bailey (1975), but were modified on the basis of local conditions and fish behaviour. Mortalities were enumerated and removed daily.

Coded Wire Tagging

Age Class Separation: Preliminary surveys conducted during August 1982 indicated that approximately 6% of the juvenile coho population in the Birkenhead River was age 1+. In view of possible brood year specific genetic and behavioural differences which could bias subsequent analyses, all coho juveniles captured during the study were sorted by age class in order to tag each brood year with a unique tag code. Eye diameter was selected as the primary sorting criterion on the basis of data reported by Robinson (MS 1976) which indicated that eye size could be useful for rapid sorting by age class in the

field. The present study used a fixed point cutoff of 5.5 mm on the basis of preliminary survey data. Eye diameter was measured using a plastic template with circular holes calibrated in 0.5 mm increments.

Tagging Procedure: The CWT equipment and machine maintenance procedures used during the study were similar to those described by Armstrong and Argue (1977). Tagging occurred between September 20 and November 19, 1982. On each tagging day, tag implant location was checked for each tag lot by bisecting the skull of a tagged coho with a scalpel along the median plane. If the tag was not in the preferred position in the cartilaginous wedge of the skull (the chondrocranium), implant depth was adjusted and the procedure repeated until tag placement was correct. Following this check, the remaining fish were tagged.

During the tagging operation, the fish were anaesthetized using a stock Tricaine Methane Sulphonate (TMS) solution of 7.5 g per litre of water which was further diluted, as conditions dictated, in a 7.5 litre plastic basin. The two age groups were assigned separate nose molds, implant depths and tag codes. The fish were then marked by adipose fin removal, tagged, and passed through a quality control device to ensure the CWT was present. All coho juveniles with a nose-fork length greater than 45 mm were tagged, with the exception of any diseased or injured fish which were noted and excluded from tagging.

When possible, a random sample of up to 350 coho was removed from the recovery bucket throughout each tagging operation and retained for a minimum of 24-hours. These fish were examined for adipose clip quality, anomalies and CWT retention. Any coho without a CWT or with a poor clip was retagged or reclipped and the tag lot totals adjusted to reflect the numbers

released with complete adipose clips and CWT's. All other tagged fish were either immediately transported to the original trapping area and released or held until the cessation of trapping, then transported and released.

Tag Codes: Two CWT codes were used during the 1982 Birkenhead River study: age 0+ and age 1+ coho were tagged with codes 02 22 09 and 02 23 26 respectively.

Biological Sampling

In each reach, at least 25 juveniles from the age 0+ and 1+ tag groups were randomly sampled prior to release to determine the reliability of age discrimination and the average size at release. A scale smear was taken with a scalpel from the "preferred region", as defined by Clutter and Whitesel (1956), nose-fork length was measured to the nearest mm, mean wet weight (± 0.1 gram) was determined by weighing the sample in aggregate on an Ohaus triple beam balance, and eye diameter, as defined as the greatest distance between the margins of the scleral cartilage, was measured to the nearest 0.5 mm as described above.

In each reach, an additional 100 coho juveniles were sampled as above prior to tagging. These samples were more representative of the stream population than the tag lot samples since coho less than 45 mm were included; however, biases due to trap selectivity were not addressed.

Physical Sampling

Surface water temperatures were recorded daily at all trapping sites using pocket thermometers. As well, records from a continuously recording thermograph installed by the IPSFC in Reach 4 (km 15.5) were obtained for the period August 18, 1982 to January 10, 1983.

ADULT PROGRAM

Aerial Survey

The Birkenhead River was surveyed by helicopter on October 30 and November 26, 1984 in order to document the holding locations of adult coho and to provide visual estimates of spawner abundance. On each survey, the river was flown from the mouth to the limit of coho passage, approximately 27.5 km upstream. Observers wore sunglasses with polarizing filters to reduce surface glare. Sighting conditions and observations of live and dead coho were recorded on a reach specific basis.

Fish Capture

Beach Seining: The use of a 5 cm mesh beach seine (6.1 m x 30.4 m) to capture adults for disk tagging was attempted early in the program. The net was set by hand in holding pools using long end ropes; however, the technique proved ineffective and was discontinued.

Angling: Adult coho were captured by angling in the Birkenhead River during the period November 6 to November 22, 1984. Angling efforts were concentrated in several deep pools in Reach 4 where adult coho held prior to migrating past a small falls to the spawning grounds. A continuous upstream movement of fish permitted the pools to be angled on a daily basis. The fish were captured using a double barbless hook baited with small pieces of fluorescent orange wool. Captured fish were beached with the aid of a landing net, transferred to a tagging tray, disk tagged and released.

Tagging Procedure

Adult coho were disk tagged in a wooden tray (10 cm x 10 cm x 100 cm) constructed with a flexible plastic bottom and a meter stick recessed in

one side. Only adult coho were tagged; precocious males (nose-fork length less than 33 cm) were not tagged due to an expected low recovery rate.

All coho were tagged using the Petersen disk tagging system, consisting of two 2.2 cm diameter laminated cellulose acetate disks and one 0.7 cm diameter transparent plastic buffer disk threaded through centrally punched holes onto a 7.7 cm long nickel pin. The pin was inserted with pliers through the musculature and pterygiophore bones approximately 1.2 cm below the anterior portion of the dorsal fin insertion. The disk tags were arranged with one on each side of the back and with a buffer disk on the pin head side. The tags were secured by twisting the tag pin into a double knot. Green disk tags were used to reduce color contrast and thereby minimize recovery and predation biases. One disk tag per pair was numbered with a unique code for individual identification.

Each disk tagged fish received a secondary mark to allow the assessment of disk tag loss. A 0.7 cm diameter hole was punched through the operculum of each disk tagged fish using a single hole paper punch. Care was taken to ensure gill tissues were not damaged.

The following information was recorded for each fish released with a disk tag: date and location (reach) of tagging, disk tag number, nose-fork length (± 0.5 cm), sex, and presence or absence of the adipose fin. The condition of the fish at release was recorded as 1 (swims away vigorously), 2 (swims away sluggishly) or 3 (requires ventilation). Any bleeding from the gills or abdomen was also noted.

Census Procedure

Stream Surveys: The Birkenhead River was surveyed on foot on a weekly

basis during the period November 28, 1984 to January 6, 1985. On each survey, a three-person crew equipped with sunglasses with polarizing filters covered all known spawning areas, with equal survey effort in each area when possible. In each reach, live adults were enumerated visually and all carcasses were sampled (described below), cut in two with a machete to avoid counting the same fish on subsequent surveys, and returned to the stream. A long handled gaff was used to retrieve carcasses from pools and an axe was used to free carcasses from river ice.

A partial weir was installed in Reach 5 in an attempt to intercept carcasses carried downstream by the current. The weir, which spanned approximately one-half the channel, was constructed from 7.6 cm mesh plastic coated fencing supported by steel T-bar driven into the substrate at two meter intervals along a wind felled tree.

Biological Sampling: All coho carcasses recovered during the 1984 study were sampled, and all sample data were recorded on a reach-specific basis. Each carcass was first examined for a secondary mark and then for a disk tag to reduce the bias from examining disk tagged fish more closely for secondary marks than untagged fish. If a disk tag was present, the number was recorded and the tag removed from the carcass. All carcasses were measured for postorbital-hypural plate length (± 0.5 cm) and five scales were removed from each preferred region for subsequent age determination. Sex was confirmed by incising the abdomen of each carcass. Spawning success was recorded for females as a percentage based on an average fecundity of 2,500 (Wood et al. MS 1979), and as spawned or unspawned for males.

All carcasses were also examined for adipose clips. The adipose condition was recorded (unclipped, or: 1 -

complete clip, flush with dorsal surface; 2 - partial clip, nub present; 3 - questionable, appears clipped but fungus or decomposition obscured area) and for all adipose clipped individuals, the head was removed posterior to the eye orbit, placed in a plastic bag coded for the above sample data and frozen.

In order to estimate CWT retention, it was necessary to evaluate the level of CWT loss which occurred after death as a result of decomposition or scavenging. Carcass condition was recorded as fresh (gills red or mottled), moderately fresh (gills white, body firm), moderately rotten (body intact but flesh soft), or extremely rotten (skin and bones). The absence of eye(s) was also recorded because poorly placed CWT's can migrate to the eye musculature where they are vulnerable to loss by scavengers.

CWT Recovery

Coded wire tag removal was conducted under the supervision of Salmon Services Branch personnel. The heads were first thawed, then rinsed to remove sand and gravel. After dissection and repeated passes through a metal detector the CWT was located, separated from tissue and decoded under a binary microscope.

When a CWT was not initially detected, the head was passed through a strong magnetic field and the process was repeated. If a CWT was not detected, a more sensitive metal detector was used. If a CWT was still not detected, the head was X-rayed to confirm a CWT was not present.

Escapement Estimation

The escapement of adult coho salmon to the Birkenhead River was calculated from the disk tagging data using the adjusted Petersen formula (Chapman modification) (Ricker 1975):

$$N = \frac{(M + 1)(C + 1)}{(R + 1)}$$

where N = population estimate

M = number of disk tags applied

C = number of carcasses examined for disk tags

R = number of disk tags or secondary marks recovered

Confidence limits ($p < 0.05$) were calculated for the population estimate by substituting the following into the above equation:

$$R + 1.92 \pm 1.960 \sqrt{R + 1.0}$$

The above method was used to generate population estimates for the total 1984 return of adult coho. Individual estimates for the return of adipose clipped adult coho and for males and females were calculated by applying the ratio of the individual estimates to the total population estimate.

RESULTS

JUVENILE PROGRAM

Fish Capture

Coho Salmon: A total of 55,531 juvenile coho salmon were captured by expending an estimated 33,495 trap-hours (1,395.6 trap-days) effort over a 64-day trapping period (Table 1). This catch included approximately 3,400 coho juveniles which were lost from vandalized pens in Reach 2. Approximately 6,600 were subsequently captured in that area and released with CWT's.

The largest catches occurred in Reach 7, which contributed 55% of the total catch and accounted for 55% of the total trapping effort. The smallest catches occurred in reaches 9 and 5, which contributed 1% and 4% respectively to the total catch and together

Table 1. Catch of coho juveniles by reach in the Birkenhead River system, 1982

Location	Trapping period	Trap-hours	Trap-days	Coho catch	CPUE	
					Trap-hr.	Trap-day

Table 3. Summary of coho coded wire tagging results by age class in the Birkenhead River system, 1982 (data from Appendix 3).

Age	Number processed	Estimated post-tagging mortality	Adipose only and tag loss	Poor adipose clip	Number released with clips and CWT's	Tag code
0+	44,875	187	168	954	43,566	02 22 09
1+	3,553	13	6	102	3,432	02 23 26

accounted for 10% of the total trapping effort. Coho catch per trap-hour and trap-day averaged 1.66 and 39.8 respectively during the 1982 program.

Nonsalmon Species: A total of 64 sculpins (*Cottus sp.*), 53 Dolly Varden char (*Salvelinus malma*), 50 rainbow trout (*Salmo gairdneri*), 27 cutthroat trout (*Salmo clarki clarki*), 6 lamprey and 2 mountain whitefish (*Prosopium williamsoni*) were captured during 1982 (Table 2). Sculpins were confined to the lower reaches; other species were captured in most areas.

Coded Wire Tagging

A total of 44,875 age 0+ and 3,553 age 1+ coho juveniles were adipose clipped and coded wire tagged during 1982 (Table 3, Appendices 3a and 3b). When adjustments were made for short term (24-hour) tag loss, mortality and incomplete adipose clips, the number released with tags and identifiable adipose clips was 43,566 age 0+ and 3,432 age 1+ coho. Due to operational problems, approximately 25% of the tagged fish were not subsampled for adipose clip quality and tag retention; average values were applied to those tag groups and release values were adjusted accordingly.

coho averaged 0.4%, with a daily tag lot range of 0% to 1.1%; delayed tag loss for age 1+ coho averaged 0.2%, with a daily tag lot range of 0% to 0.5%. Post-tagging mortality was generally low (187 age 0+ and 13 age 1+) with the exception of unusually high mortalities in the October 18 and 21 tag groups which resulted from poor pen placement during high flows.

The incidence of poor adipose fin clips for age 0+ coho averaged 2.3%, with a daily tag lot range of 0% to 8%; the incidence of poor fin clips for age 1+ coho averaged 3.1%, with a daily tag lot range of 0.4% to 9.3%. The high incidence of poor clips was attributed to staff inexperience.

The incidence of disease, damage and structural anomalies among age 0+ and age 1+ coho subsamples held for at least 24-hours was 1.7% and 18.4% respectively (Appendices 4a and 4b). Among age 0+ coho, anomalies were infrequent; among age 1+ coho, the most prevalent conditions were nose damage (14.9%) and scale loss (1.9%), both of which were associated with abrasion against the sides of the pens during the protracted holding period. The incidence of naturally missing adipose fins was 0.06% and 0% among age 0+ and 1+ coho respectively and is unlikely to effect subsequent assessment.

Short term tag loss for age 0+

Delayed Tag Loss: Delayed CWT

* Weighted mean age composition used due to inadequate sample size.

loss was assessed in tagged individuals which had migrated from the original area of release to recapture sites in other areas. A total of 670 age 0+ and 26 age 1+ coho juveniles were recaptured between 7 and 60 days after release (Appendix 3c). The incidence of tag loss in age 0+ and age 1+ juveniles was 1.0% and 7.7% respectively, an increase from the short term tag loss level of 0.4% and 0.2% respectively.

Tag Group Sampling

Age Composition: Scale-age verifications from each CWT release group (Appendix 5) were weighted by release group size to estimate the true age

composition of the coho juveniles released with CWT's (Table 4). The CWT releases consisted 95.8% of age 0+ and 4.2% of age 1+ coho juveniles. This proportion was identical to that observed in the more representative catch samples (Appendix 6); however, only 92.7% of the juveniles released with CWT's were tagged with the age 0+ code. The larger age 0+ juveniles tended to be misidentified as age 1+ juveniles, resulting in an estimated 1,451 age 0+ juveniles released with the age 1+ tag code (code 02 23 26) (Table 4). The age 0+ code (code 02 22 09) consisted entirely of age 0+ juveniles. As a result, an estimated 96.8% and 100% of the age 0+ and age 1+ juveniles respectively were re-

^a Weighted by CWT release group size.

leased with the correct code.

Length and Weight: The mean length and weight of coho juveniles released with CWT's is reported in Appendix 5 and summarized in Table 5. The age 0+ (code 02 22 09) and age 1+ (code 02 23 26) release groups averaged 55.8 mm and 1.99 g, and 84.7 mm and 7.02 g respectively. Little reach-specific variability was noted in the size of age 1+ juveniles released with CWT's; however, age 0+ juveniles from the upper reaches were smaller while age 0+ juveniles from Warbonnet Creek, a small Reach 2 tributary, were significantly ($p < 0.05$) larger than those released in other areas.

Water Temperature

Mean daily water temperatures in the Birkenhead River are detailed in Appendix 7 and Fig. 4. Temperatures declined from 12.8° C in August to 1.9° C in December. Maximum daily temperatures during the period of tagging ranged from 16° C to 30° C and were not a factor in juvenile mortality during the study.

ADULT PROGRAM

Run Timing

The 1984 Birkenhead River coho run arrived in the river in October

and, on the basis of observations during disk tagging operations, most of the run had entered the river by mid-November. Coho adults held in main-stem pools for several weeks prior to moving onto the spawning grounds. Major holding areas were located in reaches 3, 4 and 5, with smaller holding pools located throughout the upper reaches (Appendix 8).

Spawning was first observed in late November; peak spawning and die-off occurred in mid and late December respectively. Spawning continued through the end of the study and, based on the number of adults holding at that time, presumably continued into February.

The migratory timing of Birkenhead River coho through the lower Fraser River was estimated from CWT recoveries in the gill net test fishery at Albion. Birkenhead River coho were

recovered by the test fishery on October 23 (2 recoveries), November 13 (1) and November 15 (1), and a coho marked with a spaghetti tag in the Harrison River on October 15 was recovered on the spawning grounds on December 19. These data indicate that Birkenhead River coho passed through the lower Fraser River between mid October and mid November.

Spawner Distribution

In 1984, Birkenhead River coho were observed spawning in the main-stem, side channels and tributaries of reaches 3 through 10 (Appendix 8). Spawners were not observed in reaches 1 or 2, although coho were observed holding in Reach 2 during the November 26 aerial survey. The majority of coho spawned in reaches 5, 6 and 8, with 42% (431 fish) of the carcasses recovered in Reach 8 (Table 6). Observed distributions are described in

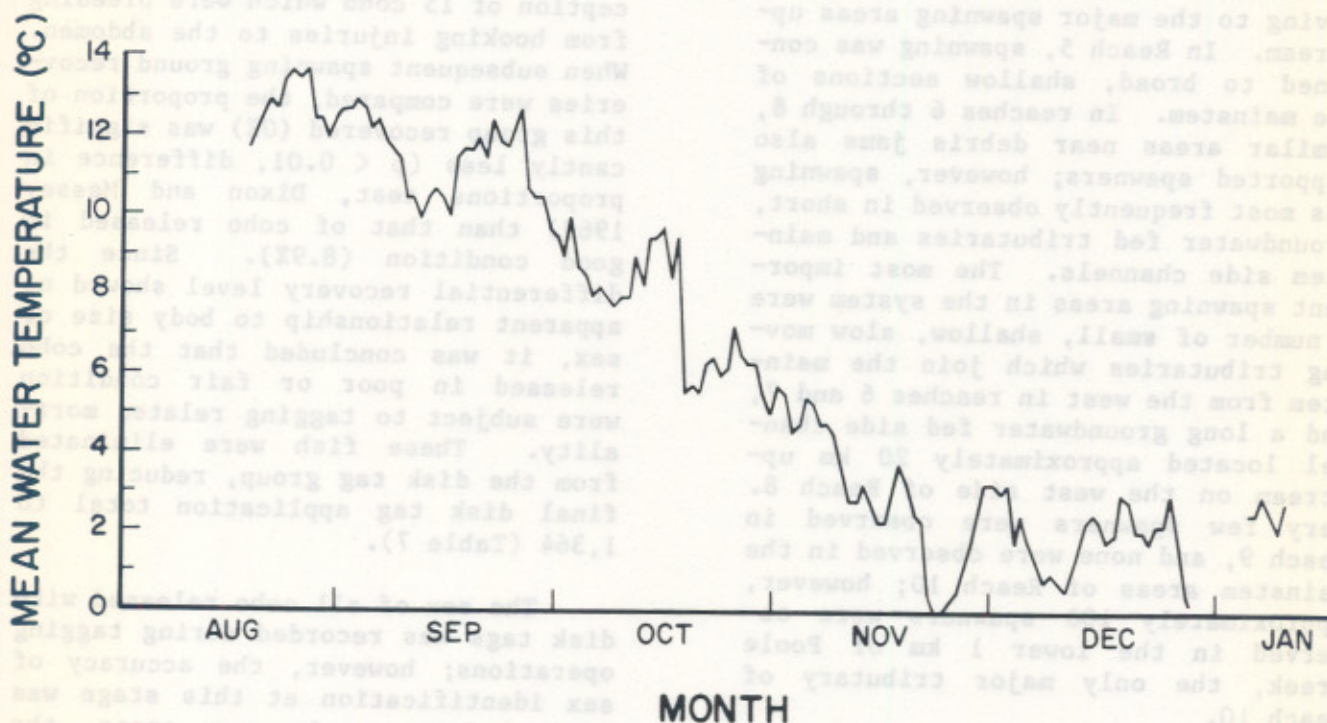

Figure 4 Mean daily water temperature in the Birkenhead River, August 18, 1982 to January 10, 1983

Table 6. Distribution of adult coho carcasses recovered in the Birkenhead River system, 1984 (data from Appendix 8).

Adipose Clips	0	0	1	3	6	16	10	43	0	0	79

detail below.

In reaches 3 and 4, scattered spawning was observed in isolated gravel deposits associated with large boulders. These reaches were used primarily as holding areas, especially a series of pools near a small falls in Reach 4 where coho held prior to moving to the major spawning areas upstream. In Reach 5, spawning was confined to broad, shallow sections of the mainstem. In reaches 6 through 8, similar areas near debris jams also supported spawners; however, spawning was most frequently observed in short, groundwater fed tributaries and mainstem side channels. The most important spawning areas in the system were a number of small, shallow, slow moving tributaries which join the mainstem from the west in reaches 6 and 7, and a long groundwater fed side channel located approximately 20 km upstream on the west side of Reach 8. Very few spawners were observed in Reach 9, and none were observed in the mainstem areas of Reach 10; however, approximately 100 spawners were observed in the lower 1 km of Poole Creek, the only major tributary of Reach 10.

Estimation of Spawner Population

Disk Tag Application: A total

of 1,379 adult coho salmon were released with disk tags and a further 11 precocious males were released untagged during the period November 6 to November 22, 1984 (Appendix 9). The condition of disk tagged fish at release was generally good, with the exception of 15 coho which were bleeding from hooking injuries to the abdomen. When subsequent spawning ground recoveries were compared, the proportion of this group recovered (0%) was significantly less ($p < 0.01$, difference in proportions test, Dixon and Massey 1969) than that of coho released in good condition (8.9%). Since the differential recovery level showed no apparent relationship to body size or sex, it was concluded that the coho released in poor or fair condition were subject to tagging related mortality. These fish were eliminated from the disk tag group, reducing the final disk tag application total to 1,364 (Table 7).

The sex of all coho released with disk tags was recorded during tagging operations; however, the accuracy of sex identification at this stage was limited because, in many cases, the development of sexually dimorphic traits was not advanced and internal examinations could not be made. To

Table 7. Summary of disk tag application and adult recovery results by sex and adipose clip status.

Group	Disk tags applied	Carcasses examined	Recoveries			Recovery rate (%)
			Secondary mark only	Disk tag	Total	
Males	818*	511	3	69	72	8.7
Females	546*	518	1	48	49	9.2
Adipose Present	1,295	950	2	106	108	8.3
Adipose Absent	69	79	2	11	13	18.8
Total	1,364	1,029	4	117	121	8.9

* Adjusted for incorrect identification.

test the accuracy of sex identification at tagging, recorded sex at application and recovery were compared for the 117 disk tagged coho recovered on the spawning grounds (Appendix 10). An estimated 6.3% of the females and 5.8% of the males were misidentified during disk tag application. When these estimates were applied to the disk tag release data, an estimated 818 (60.0%) males and 546 (40.0%) females were released with disk tags.

Carcass Recovery: A total of 1,030 coho salmon carcasses were recovered during foot surveys conducted between November 20, 1984 and January 6, 1985 (Table 7, Appendix 8). Of that total, 511 (49.6%) were adult male, 518 (50.3%) were adult female and 1 (0.1%) was a precocious male, 121 (11.7%) had disk tags or secondary marks and 79 (7.7%) had adipose clips.

The incidence of carcasses marked with disk tags or secondary marks ranged from 5.0% to 14.0% between time periods (Table 8) and from 0% to 28.6% between reaches (Table 9); however, a difference in proportions test showed no significant difference ($p < 0.05$)

between recovery periods or reaches, except the mark incidence in reaches 2 and 3 was significantly less than that in other reaches. Since very little spawning occurred in reaches 2 or 3 (Appendix 8), this bias should have little effect on study results.

The incidence of carcasses marked with adipose clips ranged from 4.4% to 10.0% between time periods (Table 8) and from 0% to 10.0% between reaches (Table 9); however, as noted with disk tag recoveries, no significant difference ($p < 0.05$) in adipose clip incidence was noted between recovery period or between reaches, except the incidence in Reach 5 was significantly less than in Reach 8.

Disk Tag Loss: Of the 121 carcasses recovered with disk tags or secondary marks, 117 had both disk tags and secondary marks, 4 had secondary marks only and none had disk tags only (Table 7, Appendix 8). The disk tag and secondary mark loss rates were 3.3% and 0% respectively.

Elapsed Time to Recovery: Elapsed time between disk tag application

Table 8. Summary of disk tag and adipose clip incidence by recovery period.

Recovery period	Total recoveries	Disk/secondary mark		Adipose mark	
		Number	%	Number	%

Total	832	532	1364	72	49	121	8.9

and recovery averaged 40.5 days and ranged from 17 to 59 days (Appendix 10). The mean elapsed time for males was slightly greater than for females, averaging 42.5 and 37.7 days respectively.

Recovery Selectivity by Length and Sex: Size related biases in the disk tag application and carcass recovery samples were examined using a Kolmogorov-Smirnov two-sample test (Sokal and Rohlf 1981). Bias in the application sample was assessed by comparing the continuous length frequency distributions of the disk tagged and untagged spawning ground recoveries. No differences were noted ($D = 0.11$; $D_{0.05} = 0.13$) indicating that the samples were drawn from the same distribution and that the application sample was unbiased with respect to size.

Recovery bias was assessed by partitioning the application sample into recovered and nonrecovered components and comparing the respective continuous length frequency distributions. The distributions were significantly different ($D = 0.22$; $D_{0.05} = 0.13$) indicating the recovery sample was biased with respect to size. This

bias was more obvious when disk tag application and recovery data were stratified in 10 cm increments of nose-fork length and recovery rates calculated for the pooled data (Table 10). Recovery rates increased with size class, ranging from 0% in the 31-40 cm class to 25.0% in the 81-90 cm class. With the exception of the 81-90 cm class, the difference in recovery rates between classes was statistically significant ($p < 0.05$; difference in proportion test).

Sex related biases were examined by partitioning the application and recovery samples as above and comparing the sex compositions within each (Table 11). The sex ratios of recovered and nonrecovered disk tagged coho were not significantly different ($p < 0.05$; difference in proportion test), indicating the recovery sample was unbiased with respect to sex; however, the proportion of males was significantly ($p < 0.05$) higher in disk tagged versus untagged spawning ground recoveries, indicating the application sample was biased toward males.

Population Estimates: The 1984 escapement of Birkenhead River coho adults, calculated from data reported

Table 11. Sex composition of disk tag application and spawning ground recovery samples.

	Disk application sample			Spawning ground sample		
	Recovered on spawning ground	Not recovered	Total	Disk or secondary mark present	Disk or secondary mark absent	Total
% Male	59.5	60.0	60.0	59.5	48.4	49.7
% Female	40.5	40.0	40.0	40.5	51.6	50.3
Sample Size	121	1,243	1,364	121	908	1,029

in Table 7, was 11,524 (Table 12). The upper and lower confidence limits were 13,743 and 9,656 respectively. The population estimates for males and females of 5,795 and 5,729 respectively were calculated by applying the ratio of the individual mark-recapture estimates to the total population estimate. The sum of the individual estimates was not significantly different ($p < 0.05$) from the combined male/female total. The escapement of precocious males, calculated from the observed incidence of precocious males in the disk tag application sample (0.79%), was 92.

Peak spawner counts obtained during aerial and foot surveys were substantially less than the above estimate of total escapement (Appendix 8). The peak aerial count of 6,145 underestimated the actual escapement by 47%; the peak foot count of 3,276 obtained on December 5 and 6 underestimated the actual escapement by 72%. Both counts were well below the lower 95% confidence limit for the 1984 population estimate.

Biological Sampling

Age Composition: The age composition of coho salmon sampled on the

spawning grounds is summarized in Table 13. Scale-age verification was completed on 929 samples, of which 29 were age 43, 899 were age 32 and 1 was age 33. Size selective sampling biases inherent to spawning ground surveys (discussed below) likely resulted in an underestimation of the precocious male (ages 33 and 22) component of the population. To correct this bias, the spawning ground age sample for adults was applied to the population estimate of 11,524 adults and 92 precocious males, producing an age composition of 3.1% age 43, 96.1% age 32 and 0.8% age 33 or 22.

Two unique growth patterns were noted in the fresh water residency period of age 43 coho. The first had closely spaced circuli in both the first and second years and a definite fresh water annulus; the second had finely spaced circuli in the first year and much wider spacing in the second year. These patterns suggest that a component of the age 43 Birkenhead River stock may leave the river and rear for extended periods in lacustrine or estuarine areas.

Length Distribution: Mean nose-fork lengths (NF) from disk tag application samples and mean postorbital-

² Nose-fork lengths.

Note - disk tag application samples were not adjusted for incorrect sex identification. Adjusted estimates are 60.0% males and 40.0% females.

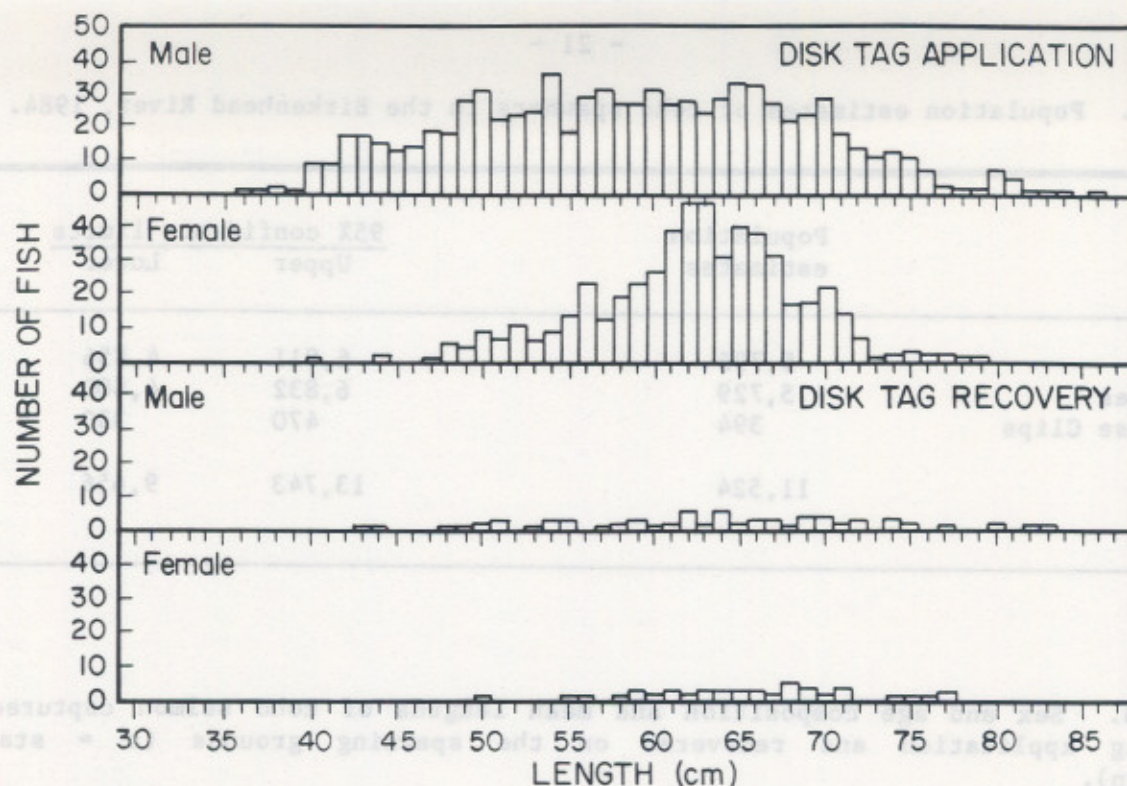

Figure 5 Nose-fork length frequency distributions by sex of Birkenhead River coho salmon which were disk tagged and subsequently recovered on the spawning grounds, 1984

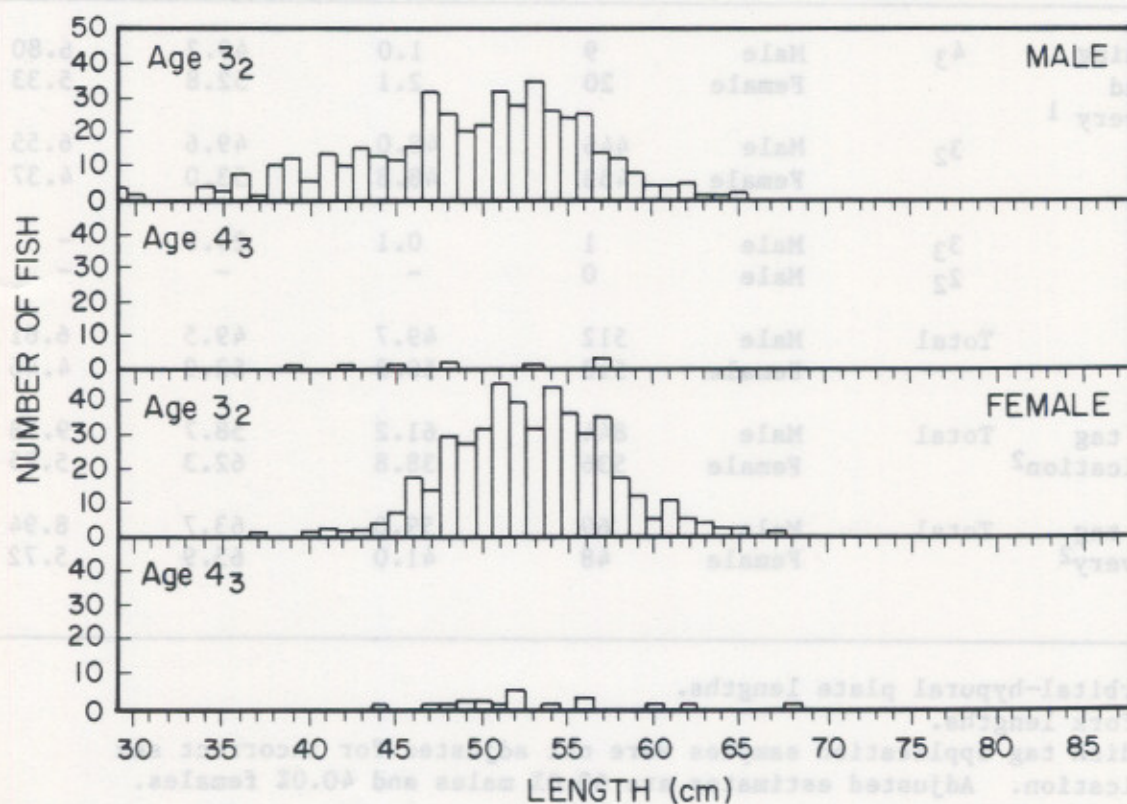

Figure 6 Postorbital-hypural plate length frequency distributions by sex and age of Birkenhead River coho salmon recovered on the spawning grounds, 1984

hypural plate lengths (POHL) from spawning ground samples are summarized in Table 13 and Figs. 5 and 6. POHL lengths of males and females averaged 49.5 ± 0.6 cm and 52.9 ± 0.4 cm. Mean POHL lengths of age 43 and 32 coho were not significantly different ($p < 0.05$) (Table 12).

NF lengths of males and females sampled during disk tag application averaged 58.7 ± 0.7 cm and 62.3 ± 0.5 cm respectively. NF lengths of disk tagged males and females subsequently recovered on the spawning grounds were significantly larger ($p < 0.05$), averaging 63.7 ± 2.1 cm and 65.9 ± 1.7 cm respectively, reflecting the size related bias in the recovery sample.

A significant correlation was noted between POHL and NF lengths of 69 males ($r = 0.91$; $p < 0.05$) and 48 females ($r = 0.86$; $p < 0.05$) which were disk tagged and subsequently recovered on the spawning grounds (Appendix 10). Predictive regressions for these data are as follows:

Adult Males:	POHL = $0.69 \text{ NF} + 6.32$
	NF = $1.31 \text{ POHL} - 2.40$
Adult Females:	POHL = $0.71 \text{ NF} + 7.06$
	NF = $1.22 \text{ POHL} + 0.34$

Sex Ratio: Adult males and females comprised 60.0% and 40.0% respectively of the disk tag application sample, 49.7% and 50.3% respectively of the spawning ground sample (Table 13) and 50.3% and 49.7% respectively of the final Petersen population estimate (Table 12). Precocious males comprised 0.8% of the disk tag application sample and 0.1% of the spawning ground sample.

Coded Wire Tag Recoveries

The incidence of coho adults with adipose clips was higher in the spawning ground sample than in the disk tag application sample, totalling 7.7% and 5.1% respectively (Appendices 8 and 9). Due to unquantified sampling

biases associated with both samples, neither ratio was used to estimate the total return of adipose clipped coho. Instead, a total return of 394 adipose clipped coho was estimated by applying the ratio of the individual mark-recapture population estimates of adipose clipped and unclipped coho to the pooled mark-recapture estimate.

A total of 79 adipose clipped carcasses were recovered during spawning ground surveys in 1984 (Appendices 8 and 11; Table 14). Of those, dissection yielded 64 with code 02 22 09, six with code 02 23 26, seven without a CWT and two CWT's which were lost during processing. The estimated total return by tag code was determined by applying the above proportions to the estimated return of adipose clipped coho, yielding 327 code 02 22 09 and 31 code 02 23 26.

Age at return was estimated as 98.2% and 83.3% age 32 for codes 02 22 09 and 02 23 26 respectively, the remainder being age 43 (Table 15). The age composition of code 02 22 09 was not significantly different ($p < 0.05$; difference in proportions test) than expected from the age sample at release. The age composition of code 02 23 26 was significantly different ($p < 0.05$) at recovery, however, with more younger individuals observed.

CWT Loss: The incidence of CWT loss in the 79 adipose clipped spawning ground recoveries was 9.1% (Table 14). It was not possible to assess the impact of carcass condition on CWT loss due to the uniformity in carcass condition; however, the incidence of CWT loss was not significantly ($p < 0.05$) influenced by the activities of predators (Table 16).

Estimated Survival: Before calculating the survival from juvenile release to spawning ground recovery, the release data were adjusted to reflect the long term incidence of CWT loss of 9.1%. The estimated survival

Table 14. Summary of juvenile releases, spawning ground recoveries and survival by CWT code in the Birkenhead River, 1984.

Code	Number released*	Spawning ground recoveries		Estimated total return	Survival (%)
		Number	%		
02 22 09	39,754	64	83.1	327	0.82

Code	Age at release			Age at recovery		
	n	Age 0+	Age 1+	n	Age 32	Age 43
02 22 09	281	100.0	0.0	56	98.2	1.8
02 23 26	197	42.2	57.8	6	83.3	16.7

Table 16. Incidence of CWT loss by carcass condition and eye status in adult coho carcasses recovered on the Birkenhead River spawning grounds, 1984.

Group	Sample size	CWT absent	CWT loss (%)
Condition 1	1	0	0.0
Condition 2	7	1	14.3
Condition 3	66	5	7.6
Condition 4	3	1	33.3
Eyes present	64	6	9.4
Eyes absent	13	1	7.3

(and 95% confidence limits) from juvenile release to adult recovery for codes 02 22 09 and 02 23 26 was 0.82% (0.69% to 0.98%) and 0.99% (0.83% to 1.18%) respectively (Table 14). These survivals do not include jack returns, fishery recoveries or returns of age 43 adults in 1985/6.

DISCUSSION

JUVENILE AGE CLASS SEPARATION

Considerable difficulties were encountered during the study in correctly sorting coho juveniles by age class. As a result, approximately 42% of the age 1+ CWT group consisted of age 0+ juveniles. This reflected in part both staff inexperience and the comparatively crude technique used to measure eye diameter; however, the error may also be attributed to a large amount of overlap between age classes in both eye diameter and body size. In a similar study in the upper Pitt River system, it was concluded that when considerable overlap existed in morphological features, a subjective technique involving both body length and eye size was considerably more effective than a fixed point cut-off using a single morphological fea-

ture (Schubert and Fedorenko 1985). This technique may have proved more effective in the Birkenhead study.

DELAYED TAG LOSS

The observed increase in the incidence of CWT loss with time in Birkenhead River coho salmon (Table 17) was consistent with assessments in U.S. hatcheries which reported that CWT loss was virtually complete within one month of tag application (Bergman *et al.* 1968; Blankenship 1981). The final level of CWT loss of 9.1% was virtually identical to the levels reported in coho spawning ground recoveries in the upper Pitt River (9.2%) (Schubert and Fedorenko 1985) and in the Cowichan-Koksilah River (9.3%) (Lister *et al.* 1981). Estimates of short term CWT loss in these studies ranged from 0.4% to 3.7% suggesting that, within limits, long term CWT loss may be independent of CWT loss assessed after 24-hours. This suggests that, while assessment of short term CWT loss may provide important feed-back regarding CWT machine and operator performance, it does not provide useful projections of the level of CWT loss during the period of recruitment to the fisheries.

Table 17. Incidence of CWT loss in Birkenhead River coho salmon over short (24-hours), intermediate (up to 60 days after tagging) and long (adult recovery) time periods. Sample sizes are bracketed.

Code	CWT loss (%)		
	Short term	Intermediate	Long term
02 22 09	0.4 (5,265)	1.0 (670)	-
02 23 26	0.2 (2,278)	7.7 (26)	-
*Mean	0.4 (7,543)	1.5 (696)	9.1 (79)

* Weighted by tag lot size.

RUN TIMING

Previous assessments of coho run timing in the Birkenhead River have reported considerably earlier timing than observed in 1984. Fishery officers reported the start, peak and completion of spawning occurred in late October, mid November and early December respectively (Brown *et al.* 1979). A more intensive assessment during 1982 reported the start, peak and completion of spawning occurred in late October, late November/early December and late January respectively (Cook MS 1983), approximately 1 to 4 weeks earlier than the timing observed in 1984. While run timing during 1984 may have been somewhat late, the results of the more intensive surveys conducted during 1982 and 1984 suggest that previous reports of run timing may have been in error.

POPULATION ESTIMATES

Sampling Selectivity

An evaluation of bias in the disk tag application sample indicated that the angling gear used by this study was selective toward males but was not selective with respect to size. The apparent lack of size selective bias was generally consistent with results reported in the literature. Leclerc and Power (1980) reported that fly fishing was the least selective of four different gears in sampling brook char (*Salvelinus fontinalis*) and ouananiche (*Salmo salar*) in a Quebec River. Bryan (1974) observed no selective bias when sampling Arctic grayling (*Thymallus arcticus*) using spinners with fluorescent orange wool but reported the same gear select larger Arctic char (*Salvelinus alpinus*). Leclerc and Power (1980) defined the selective range of angling gear at the lower limit by the largest hook and bait a small fish can take in it's mouth and at the upper limit by the smallest size of prey of interest to a

large fish and by the ability of the hook to hold a large fish without tearing or breaking. The hook size and lure used in the Birkenhead study were considered appropriate to the entire adult coho size range; however, gear selection could not address sampling biases associated with aggression or social hierarchy which may have resulted in the selective bias toward males.

In contrast to the application sample, the spawning ground recovery sample was unbiased by sex but significantly biased toward larger fish. The apparent lack of sex related recovery bias contrasts with other studies which have reported substantially higher spawning ground recovery rates of females in coho (Eames and Hino 1981; Eames *et al.* 1981), pink (Ward 1959) and sockeye (Petersen 1954) which were attributed to sex related behavioral differences. The equal recovery rates observed in Birkenhead River coho likely reflect the extremely low flows during the spawning period and the concentration of spawning in protected side channel and tributary areas. Both factors would tend to minimize displacement downstream by males, the factor most commonly cited as the cause of lower recovery rates in males.

It is unlikely that sample selectivity resulted in a biased population estimate in the 1984 Birkenhead River study. Junge (1963) demonstrated that selectivity can exist in both application and recovery samples without introducing population estimation biases if the sources of selectivity are independent, and if the source of selectivity in the recovery sample is independent of mark status. Both conditions were met in the Birkenhead River study.

Three general conclusions can be drawn from the above. First, despite size and sex related sampling selectivity, it is unlikely that the 1984

population estimate was biased. Second, spawning ground enumeration samples are size selective and provide biased estimates of the size-frequency distribution and other parameters of the population. Third, when spawning ground surveys are used for the census sample in mark-recapture studies, it becomes important to eliminate selectivity in the mark application sample or to ensure that the biases in the two samples are dissimilar. The use of angling gear for disk tag application is well suited to this type of study due to an absence of size selective bias and to a sex selective bias which is opposite to that reported in most spawner surveys.

CWT Return

The incidence of adipose marked coho in the spawning ground sample (7.7%) was substantially higher than in the population (3.4%). This bias resulted from a higher recovery rate of adipose marked individuals (Table 7) which may have reflected behavioral differences between the mainstem and tributary/side channel components of the stock. Juvenile trapping efforts focused on high density rearing areas in side channels and tributaries rather than in mainstem areas where rearing was more dispersed. Adult carcasses were likely recovered at a higher rate in these areas due to a lower rate of downstream displacement during high flows. If a relationship existed between spawning location and late summer rearing area, the above factors could result in a higher recovery rate of adipose marked coho. Studies which apply CWT's to rearing juveniles should, therefore, avoid estimating spawning ground return by applying the observed CWT incidence in the spawning ground recovery sample to an independent population estimate.

SUMMARY

1. A coded wire tag assessment of Birkenhead River coho salmon was conducted to document the exploitation rate, catch distribution and survival rate of this stock. Juvenile coho salmon were captured with minnow traps and coded wire tagged during the period September 15 to November 18, 1982. Adult spawners were enumerated by a mark-recapture study conducted during the period October 30, 1984 to January 6, 1985.
2. A total of 44,875 age 0+ and 3,553 age 1+ coho were adipose clipped and coded wire tagged. When adjustments were made for short term (24-hour) CWT loss, poor clip quality and mortality, an estimated 43,566 age 0+ coho (code 02 22 09) and 3,432 age 1+ coho (code 02 23 26) were released with adipose clips and coded wire tags.
3. The incidence of coded wire tag loss was assessed over short (24-hour), intermediate (up to two month) and long (two years) time periods. Tag loss increased from the short term incidence of 0.4%, to an intermediate incidence of 1.5%, and to a final spawning ground incidence of 9.1%. The final incidence of tag loss appeared unrelated to the incidence at release.
4. Coho juveniles were sorted by age class using a fixed point cutoff in eye diameter. Sample results at release indicated that the age 0+ code was composed entirely of age 0+ fish, and the age 1+ code was composed of 42% age 0+ and 58% age 1+ coho.
5. Age 0+ coho released with CWT's averaged 55.8 mm and 1.99 g. Age 1+ coho averaged 84.7 mm and 7.02 g.

6. The 1984 spawner escapement was estimated from a disk tag application sample of 1,364, a census sample of 1,029 and a recovery of 121 disk tagged coho. The escapement was estimated at 11,524 adult coho, of which 5,795 were males, 5,729 were females and 394 were adipose clipped. A further 92 precocious males also returned in 1984.
7. The estimated return to the spawning grounds of codes 02 22 09 and 02 23 26 were 327 and 31 respectively. Survival from release to spawning ground recovery (excluding fishery catch and returns of precocious males) was 0.82% for code 02 22 09 and 0.99% for code 02 23 26.
8. The age composition of the 1984 spawner escapement was 3.1% age 43, 96.1% age 32 and 0.8% precocious male.
9. Postorbital-hypural plate lengths of male and female coho salmon recovered on the spawning grounds averaged $49.5 \text{ cm} \pm 0.6 \text{ cm}$ and $52.9 \text{ cm} \pm 0.4 \text{ cm}$ respectively. No difference was noted in the mean length of age 43 and 32 recoveries.
10. The angling gear used to obtain the disk tag application sample was biased toward males but unbiased with respect to fish size. The spawning ground recovery sample was biased toward larger fish but unbiased with respect to sex. These sampling biases, however, did not bias the final population estimate.

ACKNOWLEDEMENTS

The authors wish to thank the following for their field work: L. Burt, A. Bussell, B. Illerbrun, D. Lantz, P. Nelson, E. Paquette, R.

Paquette and A. Rockandel. We are also grateful to M. Farwell, R. Harrison, D. Hickey, A. MacDonald and K. Wilson for reviewing the manuscript and to Y. Yole for analysing all scales. Special thanks to R. Olmsted for his adult capture efforts during 1984. Thanks also to C. MacKinnon and W. Foye for graciously providing crew accomodation during the adult study. The juvenile portion of this study was partially funded by CEIC. The manuscript was typed by R. Reimer.
