## **Canadian Technical Report of Hydrography and Ocean Sciences**

Technical reports contain scientific and technical information that contributes to existing knowledge but which is not normally appropriate for primary literature. The subject matter is related generally to programs and interests of the Ocean Science and Surveys (OSS) sector of the Department of Fisheries and Oceans.

Technical reports may be cited as full publications. The correct citation appears above the abstract of each report. Each report is abstracted in *Aquatic Sciences and Fisheries Abstracts* and indexed in the Department's annual index to scientific and technical publications.

Technical reports are produced regionally but are numbered nationally. Requests for individual reports will be filled by the issuing establishment listed on the front cover and title page. Out of stock reports will be supplied for a fee by commercial agents.

Regional and headquarters establishments of Ocean Science and Surveys ceased publication of their various report series as of December 1981. A complete listing of these publications is published in the *Canadian Journal of Fisheries and Aquatic Sciences*, Volume 39: Index to Publications 1982. The current series, which begins with report number 1, was initiated in January 1982.

## **Rapport technique canadien sur l'hydrographie et les sciences océaniques**

Les rapports techniques contiennent des renseignements scientifiques et techniques qui constituent une contribution aux connaissances actuelles, mais qui ne sont pas normalement appropriés pour la publication dans un journal scientifique. Le sujet est généralement lié aux programmes et intérêts du service des Sciences et levés océaniques (SLO) du ministère des Pêches et des Océans.

Les rapports techniques peuvent être cités comme des publications complètes. Le titre exact paraît au-dessus du résumé de chaque rapport. Les rapports techniques sont résumés dans la revue *Résumés des sciences aquatiques et halieutiques*, et ils sont classés dans l'index annuel des publications scientifiques et techniques du Ministère.

Les rapports techniques sont produits à l'échelon régional, mais numérotés à l'échelon national. Les demandes de rapports seront satisfaites par l'établissement auteur dont le nom figure sur la couverture et la page du titre. Les rapports épuisés seront fournis contre rétribution par des agents commerciaux.

Les établissements des Sciences et levés océaniques dans les régions et à l'administration centrale ont cessé de publier leurs diverses séries de rapports en décembre 1981. Une liste complète de ces publications figure dans le volume 39, Index des publications 1982 du *Journal canadien des sciences halieutiques et aquatiques*. La série actuelle a commencé avec la publication du rapport numéro 1 en janvier 1982.

## ABSTRACT

Minns, C. K. 1986. A model of bias in lake selection for survey. Can. Tech. Rep. Fish. Aquat. Sci., 1496:i-v, 1-21pp.

The purpose of this report is to describe the results of analyses of the Ontario lake inventory data base. Models of selection bias are developed from a model of predator preference. The models are used to estimate the selection bias toward lakes containing four gamefish species, brook trout, lake trout, smallmouth bass and walleye. The results suggest that co-occurrences of these species are overrepresented in the data base and that unsurveyed lakes, if they have gamefish, will likely only have one of the four species present. Alternative schemes for eliminating or accommodating the biases are discussed.

## RESUME

Minns, C. K. 1986. A model of bias in lake selection for survey. Can. Tech. Rep. Fish. Aquat. Sci., 1496:i-v, 1-21pp.

Le présent rapport vise à décrire les résultats des analyses de la base de données de l'inventaire des espèces de poissons du lac Ontario. Des modèles d'erreur systématique de choix sont élaborés à partir d'un modèle de préférence des prédateurs. Les modèles servent à évaluer l'erreur systématique de choix à l'égard de lacs contenant quatre espèces de poissons-gibier (omble de fontaine, touladi, achigan à petite bouche et doré). D'après les résultats, la présence simultanée de ces espèces est sur-représentée dans la base de données et il est probable qu'advenant la présence de poissons-gibier dans les lacs non étudiés, seule une des quatre espèces sera présente. D'autres plans pour éliminer ou adapter les erreurs sont abordés.

## LIST OF TABLES

- Table 1 Estimates of the bias coefficient  $\alpha$  given  $n_a$ ,  $n_t^*$ ,  $N_t^*$  and 'guestimates' of  $N_a$  for four species of gamefish, using equation 4.
- Table 2 Expected sample of lakes containing species a and b ( $n_{ab}$ ) after biased sampling of 500 ( $n_t$ ) of 10,000 ( $N_t$ ) lakes for various combinations of  $\alpha$  and  $\beta$  using equations 7-10. (The line delimits those combinations where all available lakes with a and b are sampled.)
- Table 3 Percentage of sampled lakes with both species present versus cumulative sample size with  $N_a=100$ ,  $N_b=100$ ,  $N_{ab}=10$ ,  $N_t=10,000$  using equations 7-10.
- Table 4 Results of linear regressions of  $n_a/n_t$  vs  $n_t/N_t$  for lake trout by primary watershed and lake size range in Ontario, with and without zero values ( $n_a/n_t=0$ ).
- Table 5 Observed cumulative number of lake inventories, percentage of lakes with one or more gamefish species and percentage of lakes with one of fifteen combinations of gamefish presence/absence.
- Table 6 Assumed occurrences ( $N_i$ ) of all combinations of the four gamefish species in Ontario lakes.
- Table 7 Predicted percentage of lakes with one or more gamefish species and percentage of lakes with one of fifteen combinations of gamefish presence/absence, using the biases in Table 1.

## INTRODUCTION

According to Cox (1978) the province of Ontario has more than 180,000 lakes, each with an area of one ha. or greater. While there are a number of large lakes including the Great Lakes, the vast majority (94.1 percent) have an area less than 100 ha. Of all these lakes, approximately 9,000 have been inventoried by the Ontario Ministry of Natural Resources. Inventories are conducted using a standard procedure (Dodge et al. 1981) and are designed basically to provide morphometric and physico-chemical data plus a fish species list.

The collection of inventories conducted to date is not a random subsample of total population of lakes (Goodchild and Gale 1981). The database is biased toward large lakes (Minns 1984) and toward lakes containing certain preferred gamefish species (Minns 1981). Those species include brook trout, Salvelinus fontinalis, lake trout, Salvelinus namaycush, smallmouth bass, Micropterus dolomieu, and walleye, Stizostedion vitreum vitreum.

In recent years, the database has come to be recognized as an important source of information for a number of resource management issues (Goodchild and Gale, 1981). Those issues include: selection of lakes as class representatives for a province-wide assessment network (OMNR 1978); and identification of the potential extensive impact of acidic deposition on valued fishery resources (Minns 1981).

To extrapolate from the inventory sample to the total lake set, the database must be assumed to be representative of the total set. For instance, Minns (1981) found that 1496 out of 6393 inventoried lakes contained brook trout. If this was assumed to be representative of the total population, one

would estimate there were 42359 brook trout lakes in Ontario. However, an exhaustive search for brook trout lakes using informal information available in district and regional offices of OMNR, museum records, etc., produced an estimated total of 2110 brook trout lakes (C.H. Olver quoted in Minns 1981). Similar results were indicated for other gamefish species (Minns 1981). As the database inventory is a biased sample of the total lake set, it is essential that quantified means of correcting for biases be developed before further extrapolations are attempted.

The purposes of this report are: (1) to examine simple models of biased sampling; (2) to present the results of exploratory attempts to quantify bias in the inventory database; and (3) to suggest future sampling options whereby the bias problem may be made more manageable.

#### BIASED SAMPLING MODELS

Lakes selected for inventory are rarely resurveyed. This represents a situation of selection from a mixed population without replacement. Manly et al. (1972) developed a model to describe this phenomenon which allows for preferences, or biased selection. Recast in terms of biased selection of lakes for inventory, the model is as follows: suppose there is a total set of  $N_t$  lakes of which  $N_a$  contain fish species a. A lake containing species a is (relative preference) times more likely to be selected for inventory. If the numbers of lakes with and without species a are equal, the probability of picking a lake with a is

$$P(a) = \frac{\alpha}{1 + \alpha} \quad (1)$$

If the numbers of lakes are unequal then the coefficients must be weighted by their corresponding population sizes. Thus,

$$P(a) = \frac{Na\alpha}{(Nt-Na) + Na\alpha} \quad (2)$$

for the first lake selected. On successive selections, since lakes are not inventoried a second time, the probabilities change. After  $n_t$  lakes have been inventoried, of which  $n_a$  contained species  $a$ , the probability that the next lake inventoried contains  $a$  is

$$P(a) = \frac{(Na-na)\alpha}{[(Nt-Na)-(nt-na)] + (Na-na)\alpha} \quad (3)$$

Manly et al (1972) showed that this equation could not be integrated with respect to  $n_t$ . However, by means of approximation, they showed that an approximation could be developed as a basis for estimating  $\alpha$  from known data:

$$1 - \frac{nt-na}{Nt-Na} = \left(1 - \frac{na}{Na}\right)^{1/\alpha} \quad (4)$$

In the selection experiments all the  $n_i$  and  $N_i$  are known, so  $\alpha$  could be estimated. In the case of the inventory database both  $\alpha$  and  $Na$  are unknown.

Nonetheless, guestimates of  $N_a$  can be used to allow an approximate estimate of the degree of bias. Intensive efforts have been made to determine the number of brook trout, lake trout, and walleye lakes in Ontario (C.H. Olver, pers. comm.) and a similar attempt is now being made for smallmouth

bass. Those estimates of  $N_a$  were used along with the values of  $n_a$  after 8867 lakes had been inventoried ( $=nt$ ), to calculate approximate  $\alpha$ 's using equation (4). The results indicate the extreme degree of bias with values ranging from 13 to 45 (Table 1). Of course this rough analysis takes no account of biogeographic effects and temporal trends in the spatial allocation and intensity of sampling as the data base grew. This approach also does not account for the simultaneous action of several biases; i.e., selection for more than one fish species or other lake attributes concurrently. Difficulties involved in the detection of fish species, which may vary from species to species, are not considered here.

The presence of biases for several fish species at the same time, can lead to an overestimation of the co-occurrence of two species, as long as the proportion of the total population sampled is low; i.e.,  $n_t$  small compared to  $N_t$ . This is very important if one is trying to identify lake types based on fish species combinations for assessment purposes. In the presence of bias, one may be led to consider a combination which doesn't warrant the attention. Given the high level of bias (Table 1) toward the four gamefish species, this overattention is highly likely.

The model of Manly et al. (1972) can be used to deal with the situation where several biases are operative at the same time. Given equations (1) to (3), assume there is a second species  $b$  for which the preference is  $\beta$ . The probability of choosing a lake with  $b$  present is,

$$P(b) = \frac{\beta}{1 + \beta} \quad (5)$$

The probability of choosing a lake with both species a and b present is

$$P(a).P(b) = \frac{\alpha}{(1 + \alpha)} \cdot \frac{\beta}{(1 + \beta)} \quad (6)$$

If the frequencies of occurrence of the combinations among  $N_t$  are designated as follows,

		Species b		
		Absence	Presence	Total
Species a	Absence	$N_{oo}$	$N_{ob}$	$(N_{oo}+N_{ob})$
	Presence	$N_{ao}$	$N_{ab}$	$N_{ao}+N_{ab}=N_a$
Total		$(N_{oo}+N_{ao})$	$N_{ob}+N_{ab}=N_a$	$N_t$

the probabilities of occurrence for the four combinations after  $n_t$  lakes have been inventoried are,

$$P(oo) = \frac{(N_{oo} - n_{oo})}{D} \quad (7)$$

$$P(ao) = \frac{\alpha (N_{ao} - n_{ao})}{D} \quad (8)$$

$$P(ob) = \frac{\beta (N_{ob} - n_{ob})}{D} \quad (9)$$

$$P(ab) = \frac{\alpha\beta (N_{ab} - n_{ab})}{D} \quad (10)$$

where  $D = (N_{oo} - n_{oo}) + \alpha(N_{ao} - n_{ao}) + \beta(N_{ob} - n_{ob}) + \alpha\beta(N_{ab} - n_{ab})$ .

The probabilities can be integrated numerically from zero to  $n_t$  to determine expected frequencies. An example will illustrate the effect that two biases will have on co-occurrences. For instance, in the lake inventory data base about 20 percent of the lake trout lakes also contain brook trout. A hypothetical province (ratio to Ontario  $\approx 1:20$ ) would have 10000 lakes ( $N_T$ ) with 100 brook trout lakes ( $N_a$ ) and 100 lake trout lakes ( $N_b$ ). The data base proportion of co-occurrence is assumed to be an overestimate and so I assumed there are 10 lakes ( $N_{ab}$ ) containing both brook trout and lake trout. Sampling of 500 lakes, i.e., integration of probabilities from 0 to  $n_t=500$ , can be simulated with various values for the biases  $\alpha$  and  $\beta$ . The results show how effective the combined biases can be in inflating estimates of the co-occurrence of the two species (Table 2). In most cases, all possible co-occurrences of a and b are included in the database after only 500 of 10000 lakes set have been inventoried.

The cumulative results of bias show a pattern of declining proportions of  $n_{ab}/n_t$  (Table 3). Thus early results will give a false impression of the frequency of occurrence of combinations. The expected percentage occurrence of both species is 0.1. When a single bias is present ( $\alpha=1$ ,  $\beta=40$ ), the percent occurrence is 2 to 3 percent, many times expected. When two biases are operative the distortion is severe (Table 3). In the case of  $\alpha=40$  and  $\beta=40$ , nearly all the co-occurrences have been sampled after only 50 lakes have been inventoried. Of course this co-occurrence is only sustained until a large proportion of  $N_a$  and  $N_b$  have been sampled. Then  $n_{ab}/n_a$  and  $n_{ab}/n_b$  will approximate  $N_{ab}/N_a$  and  $N_{ab}/N_b$ .

# ANALYSIS OF SELECTION BIAS OF THE ONTARIO LAKE INVENTORY DATABASE

Two approaches to the analysis of bias in the data base were tried: one spatial and one temporal. In the spatial analysis, the inventories were aggregated by number and lake area at the tertiary watershed level by lake area size categories. The hypothesis was that as the proportion of lakes inventoried  $\frac{nt}{Nt}$  in a watershed approaches 1.0 the proportion of lakes containing a particular species  $\frac{na}{nt}$  will tend toward its true value  $\frac{Na}{Nt}$ . The values of  $na/nt$  and  $nt/Nt$  at the tertiary watershed level were aggregated at the primary watershed level and  $na/nt$  regressed against  $nt/Nt$ . For fish species for which there is a positive bias ( $\alpha > 1$ ), the slope should be negative; for species for which there is a negative bias ( $\alpha < 1$ ), the slope should be positive; for species for which there is no bias ( $\alpha = 1$ ), the slope should be zero. Results for the single-species bias model suggested that a log/log transformation might be appropriate as cumulative curves of  $na/nt$  vs  $nt/Nt$  are non-linear when  $\alpha \neq 1.0$  (bias present).

The data were aggregated at the tertiary watershed level and analysed at the primary watershed level, in order to allow for regional differences in the occurrence of fish species. The results were mixed and not very useful in assessing bias. For example the linear regressions for lake trout (Table 4), had both positive and negative slopes and correlations varied considerably (0.027 to 0.610). If tertiary watersheds where  $na/nt$  was zero were excluded (this was taken as an indication that the watershed lay outside the distribution of the species in question), results didn't improve (range of  $r$  0.034 to 0.689). One of the reasons for the poor correlations was a lack of range in the values of the independent variable ( $nt/Nt$ ). Log/log regressions gave no better results, so the spatial approach to analysis was abandoned.

In the temporal analysis, the inventories were aggregated by inventory year. Cumulative tables were calculated for the occurrences of the 16 combinations of the four gamefish species. These results show much stronger evidence of the biases (Table 5) than was obtained with the spatial analyses. The percentage of inventoried lakes containing one or more of the four gamefish species has declined from over 80 to 64 percent over the period 1961-1981. Brook trout were overrepresented early on. Various combinations of gamefish peaked in the first few years. The single occurrences of walleye, smallmouth bass, and lake trout are the only categories continuing to increase as a proportion of the total.

#### A MODEL OF BIAS FOR THE ONTARIO LAKE INVENTORY DATABASE

The rough analysis of bias for the four gamefish species produced high bias coefficients (Table 1). At that level of bias, it is to be expected that co-occurrences of the four species will have been almost completely exhausted by now. A simple model of bias can be examined assuming that all further expected occurrences of each species will be singly rather than in mixtures (Table 6). Given these expected values of  $N_i$  for all sixteen combinations and the estimated  $\alpha$ 's from Table 1, the expected cumulative sampling pattern was computed for up to 10,000 of the 181,015 lakes in Ontario. The results (Table 7) are remarkably similar to that found with the chronological analysis of the data base (Table 5). The differences between observed (Table 5) and predicted (Table 7) suggest that non-brook trout values of  $\alpha$  (Table 2) are overestimates and the brook trout  $\alpha$  an underestimate. The results do suggest

that co-occurrences have been exhausted and that future lake inventories will only find single occurrences of the four gamefish species.

The basic model of bias toward four gamefish species is a reasonable description of the cumulative lake inventory database. A more thorough model fitting would require the simultaneous estimation of the  $N_i$ 's and the  $\alpha$ 's though it is not clear if early data should be grouped to give larger sample size increments. Another analysis approach would be to examine the results of inventories made since 1981, to see if the trends in the percentage composition of gamefish mixtures have been sustained.

#### DISCUSSION

The results confirm that there are biases leading to the over-representation of certain fish species in the lake inventory data base. However, it appears that the model of Manly et al. (1972) and its extensions can be used to describe the bias. Chesson (1978) strongly endorsed the use of the Manly et al. (1972) model of selective predation, as it is one of the few that allows for differences in the frequency of occurrence of the various prey types. The results presented here strongly suggest it is an appropriate description of the biased selection of lakes for inventory.

It is not surprising that these biases should occur. These biases are in fact deliberate. Agencies charged with the management of fishery resources direct their efforts to those species which are highly prized and most exploited. However, these biases need to be understood and quantified when overall resource assessments are needed, as with the acidic deposition problem.

Given that the biases affect the inventory data base, a number of

consequences arise. Chief of these is the over-representation of co-occurrences. This causes more assessment attention to be directed their way and extrapolations down-play the role of lakes containing only one of the species. Minns (1986) found in an association analysis of the inventory database that there were three main fish assemblages - 'brook trout', 'centrarchid' and 'salmonid-percid'. Given the bias toward the top predator members of these groups, the co-occurrence of these assemblage types was likely overstated. The three types are headed by at least one of the species for which there is a strong bias. The walleye and lake trout did not appear in separate clusters as a result of the association analysis.

To extrapolate from the inventory data base, it may be necessary to treat lakes which contain more than one of the four top predators as being a complete survey and to extrapolate from the lakes which contain only one of the species.

Bias analyses of the lake inventory database are by no means complete. I have assumed that we know the number of lakes occupied by various assemblages. A more intensive analysis would involve an iterative fitting of  $N_i$ 's for each assemblage and the four  $\alpha$ 's. The analyses so far do not consider how biogeographical and habitat limitations might condition the assemblage frequencies. Likely the database should be stratified to account for regional limits on the distributions of species. Legendre and Legendre (1984) performed a biogeographical analysis on the distribution of fish in Quebec, relating patterns to postglacial dispersal and topographical barriers. Such an analysis might be a useful precursor to a further analysis of bias.

As for the future conduct of lake selection for inventory in Ontario, three options are available. If the emphasis of management remains focussed on particular species, a profitable strategy might be to increase the bias even further to make an exhaustive search for the remaining lakes containing preferred species. This approach could be aided by the biogeographic analysis suggested above and by extensive surveys based on a few key parameters identified from discriminant analyses of presence/absence as presented in Minns (1986) and Beggs et al. (1985). Such parameters would likely include lake area, maximum depth, secchi depth, and elevation.

If the emphasis of management shifts further toward a more "community"-based approach with a concern for the whole freshwater resource, a stratified random method of lake selection would have to be adopted. Resource mapping already available (Cox 1978) could be exploited by having lakes selected on a watershed and size range basis. This approach would not correct for the bias in the existing lake inventory data base.

A third option would involve targetting a large number of lakes for inventory, which do not contain any of the four gamefish species. It is highly unlikely that this option would be adopted as it would mean tens of thousands of lakes being inventoried with little management application.

Whichever approach is used, it is important that the bases for lake selection be explicit and quantified where possible. As resource management becomes ever more complicated, it is important that the data collected under the auspices of inventories and surveys be suitable for extrapolation and, after correction for bias, representative of the total resource under consideration be it all lakes or all gamefish lakes.

#### ACKNOWLEDGEMENTS

I am pleased to recognize the continuing encouragement and support from many colleagues in the Fisheries Branch, Ontario Ministry of Natural Resources including Gail Beggs, Donna Wales, John Matusek and Jim MacLean. This work was undertaken, in part, to support efforts to develop an extensive impact assessment of acidic deposition on Ontario's freshwater fishery resources.
