Canadian Technical Report of Fisheries and Aquatic Sciences No. 2129

## Canadian Technical Report of Fisheries and Aquatic Sciences

Technical reports contain scientific and technical information that contributes to existing knowledge but which is not normally appropriate for primary literature. Technical reports are directed primarily toward a worldwide audience and have an international distribution. No restriction is placed on subject matter and the series reflects the broad interests and policies of the Department of Fisheries and Oceans, namely, fisheries and aquatic sciences.

Technical reports may be cited as full publications. The correct citation appears above the abstract of each report. Each report is abstracted in Aquatic Sciences and Fisheries Abstracts and indexed in the Department's annual index to scientific and technical publications.

Numbers 1-456 in this series were issued as Technical reports of the Fisheries Research Board of Canada. Numbers 457-714 were issued as Department of the Environment, Fisheries and Marine Service Technical Reports. The current series name was changed with report number 925.

Technical reports are produced regionally but are numbered nationally. Requests for individual reports will be filled by the issuing establishment listed on the front cover and title page. Out-of-stock reports will be supplied for a fee by commercial agents.

## Rapport technique canadien des sciences halieutiques et aquatiques

Les rapports techniques contiennent des renseignements scientifiques et techniques qui constituent une contribution aux connaissances actuelles, mais qui ne sont pas normalement appropriés pour la publication dans un journal scientifique. Les rapports techniques sont destinés essentiellement à un public international et ils sont distribués à cet échelon. Il n'y a aucune restriction quant au sujet; de fait, la série reflète la vaste gamme des intérêts et des politiques du ministère des Pêches et des Océans, c'est-à-dire les sciences halieutiques et aquatiques.

Les rapports techniques peuvent être cités comme des publications complètes. Le titre exact paraît au-dessus du résumé de chaque rapport. Les rapports techniques sont résumés dans la revue Résumés des sciences aquatiques et halieutiques, et ils sont classés dans l'index annual des publications scientifiques et techniques du Ministère.

Les numéros 1 à 456 de cette série ont été publiés à titre de rapports techniques de l'Office des recherches sur les pêcheries du Canada. Les numéros 457 à 714 sont parus à titre de rapports techniques de la Direction générale de la recherche et du développement, Service des pêches et de la mer, ministère de l'Environnement. Les numéros 715 à 924 ont été publiés à titre de rapports techniques du Service des pêches et de la mer, ministère des Pêches et de l'Environnement. Le nom actuel de la série a été établi lors de la parution du numéro 925.

Les rapports techniques sont produits à l'échelon regional, mais numérotés à l'échelon national. Les demandes de rapports seront satisfaites par l'établissement auteur dont le nom figure sur la couverture et la page du titre. Les rapports épuisés seront fournis contre rétribution par des agents commerciaux.

#### Abstract

Koski, W. R., M. R. Link, and K. English. 1996. Distribution, timing, fate and numbers of chinook salmon returning to the Nass River watershed in 1992. Can. Tech. Rep. Fish. Aquat. Sci. 2129: 141 p.

Extensive radio-tagging and escapement surveys were conducted, as part of the 1992 Nisga'a Interim Measures Program (IMP), to obtain reliable run-timing and escapement estimates for all chinook salmon stocks in the Nass River watershed. A total of 360 radio tags were applied to adult chinook salmon in the lower Nass River and were tracked throughout the watershed using a combination of stationary receivers, and foot, boat, helicopter and truck-based telemetry surveys. Eight fixed-station receivers were established at strategic locations to automatically record upstream and downstream movements of radiotagged fish. Multiple antennas were used to determine the direction of travel for fish passing the receivers stationed at the junction of major tributaries. We were able to determine spawning destinations for $81 \%$ of the fish tagged and $98 \%$ of the active tags that escaped lower-river fisheries. Extensive surveys of two major tributaries and brief surveys of several other tributaries provided the mark-recapture data required to compute reliable estimates of the number of chinook escaping to each area. The total adult chinook escapement to spawning areas was roughly 17,000 fish. An additional 1,342 chinook were caught by sport fishermen, 7,100 chinook were taken by the Nisga'a fishery, and approximately 730 chinook were suspected to have been removed by other First Nations fishermen. Thus the total chinook return to the Nass River in 1992, in-river catch plus escapement, was estimated to be about 26,000 fish.

## RÉSUMÉ

Koski, W. R., M. R. Link, and K. English. 1996. Distribution, timing, fate and numbers of chinook salmon returning to the Nass River watershed in 1992. Can. Tech. Rep. Fish. Aquat. Sci. 2129: 141 p.

Une vaste campagne de radio-étiquetage et d'observation des taux d'échappée a été effectuée dans le cadre du Programme de mesures intérimaires des Nisga'a. Cette étude avait pour objet de recueillir des données fiables sur les temps de migration et les taux d'échappement des divers stocks de saumon quinnat du bassin de la rivière Nass. Au total, 350 radio-émetteurs ont été insérés sur des spécimens de saumons quinnats adultes dans le cours inférieur de la rivière Nass, et pistés à travers le bassin hydrographique au moyen de postes récepteurs fixes et de campagnes de télémesure conduites au sol (à pied et par camion), par bateau et par hélicoptère. Huit récepteurs fixes ont été installés dans divers points stratégiques pour suivre les déplacements anadromiques et catadromiques des spécimens radio-étiquetés. Plusieurs antennes ont été utilisées pour déterminer le sens de déplacement des poissons traversant les champs de captage des récepteurs situés aux points de confluence des principaux tributaires. Nous avons pu localiser les frayères de $67 \%$ des poissons étiquetés et de $95 \%$ des spécimens étiquetés ayant échappé aux opérations de pêche dans le cours inférieur de la rivière. Des recensements à grande échelle dans deux grands tributaires et à moindre échelle dans plusieurs autres tributaires ont permis de recueillir les données de récupération des spécimens marqués qui étaient requises pour estimer de manière fiable le nombre d'échappées de saumons quinnats pour chaque zone. Le nombre total d'échappées de saumons quinnats adultes vers les zones de frais a donc été établi à environ 17000 individus. Un nombre additionnel de 1342 saumons quinnats a été capturé par les pêcheurs sportifs; 7100 saumons quinnats ont été pris par les pêcheurs Nisga'a et environ 730 auraient été prélevés par d'autres pêcheurs autochtones que les Nisga'a. On en a déduit que l'effectif de remonte global de saumons quinnats dans la rivière Nass en 1992 - nombre capturé et nombre d'échappées confondus - était d'environ 26000 individus.

## INTRODUCTION

The Nass River system is the third largest river system in British Columbia and is a significant producer of chinook salmon (Oncorhynchus tshawytscha). Chinook are heavily utilized by commercial, native and sport fisheries and many chinook populations along the Pacific coast, including the Nass River stocks, may be greatly reduced from their historic levels. Hence a high level of concern has been expressed for Nass River chinook populations.

The Nisga'a Tribal Council (NTC) is currently negotiating a land claim settlement with the federal and provincial governments that may include an allocation of a part of the fisheries resources of the Nass River System to the Nisga'a. Thus, all parties have a requirement to know the following:

1. the number of chinook salmon entering the Nass River and its tributaries;
2. where these fish spawn; and
3. the timing of runs of different stocks of chinook salmon.

The Department of Fisheries and Oceans (DFO) have conducted annual surveys of chinook spawners in some of the tributaries of the Nass River, but these surveys provide only partial estimates of total escapement because:

1. some fish cannot be counted in turbid systems;
2. counts are usually conducted only once or twice each year and may not always reflect the total or peak number of fish present in each system; and
3. not all spawning areas are surveyed.
4. only partial counts are conducted for most of the systems surveyed.

Although the DFO counts provide information on relative run sizes over long periods of time, they do not provide sufficiently detailed information to manage chinook stocks effectively over a shorter time frame.

In December 1991, the federal government and the NTC signed an agreement wherein the DFO would provide funding for a fisheries Interim Measures Program (IMP). The program included a wide variety of fisheries projects designed and directed by technical representatives of the NTC and the governments of Canada and British Columbia. Two of these projects, chinook radio-tagging and chinook escapement surveys, were specifically designed to address three data requirements outlined above. In this report we present a detailed description of the field and analytical methods used to derive chinook escapement estimates for the Nass River and its major tributaries.

The quality and completeness of our assessment of 1992 returns of chinook salmon to the Nass River was significantly enhanced by information and opportunities provided through other IMP projects. The in-river sport and native catch monitoring surveys provided information on the timing of fish movements in the lower river and reliable harvest estimates
for all major fisheries. The Nass River fishwheel project provided an excellent supply of healthy adult chinook salmon for radio tagging, and field crews working at the Meziadin fishway and Kwinageese weir obtained daily counts of chinook passing these locations.

## STUDY AREA

The Nass River drains $8000 \mathrm{~km}^{2}$ and is the third largest watershed in British Columbia. The river originates in the Skeena Mountains and flows south and southwest for 400 km , entering the Pacific Ocean at Portland Inlet on the north coast of British Columbia (Fig. 1).

The Nass River supports significant populations of chinook, sockeye (Oncorhynchus nerka), coho ( $O$. kisutch), chum ( $O$. keta), and pink ( $O$. gorbuscha) salmon, as well as steelhead ( $O$. mykiss). Chinook salmon spawning areas are found throughout the Nass River watershed. Figure 1 shows 34 Nass River tributaries surveyed for chinook salmon in 1992. Sixteen of these have been identified by the DFO as containing chinook spawning areas (Table 1, L. Jantz, DFO, Prince Rupert, B.C., unpubl. data).

The life history information for chinook salmon is generally known for other systems and some stock specific data are available about the timing of movements into freshwater and about the timing of spawning in the Nass River system. Two life-history types of chinook salmon have been found in the Nass River (Godfrey 1968; Healey 1983, 1991). Godfrey (1968) indicates that $58 \%$ of the chinook spawning runs to the Nass River during 1964-66 were ocean-type fish and only $42 \%$ were stream-type. Studies in other areas have indicated that the contribution of stream- and ocean-type chinook to a spawning run can vary from year to year. Healey (1991) states that there is a tendency, at least in areas south of the Nass River, for stream-type chinook to enter the rivers earlier than ocean-type fish; however, he did not provide data on the entry dates of these two spawning types into the Nass River. Thus dates of entry and spawning for Nass River chinook stocks may vary from year to year depending on the contribution of the two life history types to the escapement for that year.

Data collected by DFO from 1950 to 1988 (L. Jantz, DFO, Prince Rupert, B.C., unpubl. data) suggests that chinook salmon begin to enter the Nass River system in early June and continue to enter until mid September with the peak period of entry being highly dependent on the stock. Spawning begins in late July and continues until early October with peak spawning occurring in mid August to early September. Die-off begins in early August and is usually completed by the end of September, but can be as late as mid November.

Chinook spawning escapement estimates have averaged 8,858 for the period 1982-91 and ranged from 3,309 in 1991 to 16,265 in 1986 (L. Jantz, DFO, Prince Rupert, B.C., unpubl. data). Table 1 provides a list of the escapement estimates by tributary for the period 1982-91. Four tributaries of the Nass River: the Damdochax, Kwinageese, Meziadin and Cranberry/Kiteen systems are reported to contain the majority of the chinook spawning areas. These four systems have been estimated to contain $46-86 \%$ of the estimated total annual Nass

River escapement from 1982-91 (Table 1). Based on the $10-\mathrm{yr}$ average estimates to each system (including only years when the system was surveyed), the escapements have averaged 10,277 and the four major systems have contributed $67 \%$ to this total (Table 1).

## METHODS

## STUDY DESIGN

Data from several sources were integrated and used to monitor movements and numbers of chinook in various parts of the Nass River and its tributaries. The data presented here were obtained during a radio-tagging study, aerial and ground counts, fishway and weir counts, and carcass counts and examinations for mark-recapture estimates. We maximized our resources by restricting intensive aerial and ground surveys to locations and time periods that had previously been documented as important to chinook salmon. Surveys were conducted of less important areas primarily during the periods of peak spawning as indicated by historical data (L. Jantz, DFO, Prince Rupert, B.C., unpubl. data). The survey effort was also influenced by the distribution and timing data obtained from tracking radio-tagged fish.

## RADIO-TAGGING STUDY

The radio-tagging study involved catching and tagging chinook salmon, steelhead and chum in the lower part of the river between Fishery Bay and Grease Harbour (Fig. 2) and tracking them using a combination of stationary radio-tag receivers; foot, boat and truckbased surveys; aerial surveys; and tag recoveries on the spawning areas after the fish had died. The information was integrated into one large database which archived the locations, dates and time when each tagged fish was tracked during field surveys.

## Methods of Capturing Fish

Chinook salmon and steelhead trout were initially captured using set and drift tangle nets. Fishwheels became the primary fish capture method when it became apparent that they were going to catch sufficient numbers of chinook to meet our tagging requirements. Nets were used only to supplement catches when one or both of the fishwheels was not operating.

Set Nets: Stationary tangle nets ( 15 cm mesh, 3 m deep and 45 m long) were used at Sandy River and Grease Harbour to capture fish for radio tagging (Fig. 2). The nets were constantly attended, except during the brief periods when the taggers moved to the release site to tag and release fish, to minimize the time that fish spent tangled in the net and to minimize the likelihood of fish injury and mortality. When fish entered the net, the net was retrieved and the fish were removed and placed in a canvas holding tank. The net was reset and the fish were transported upstream or across the river about 200 m to the release site. The release site was a calm area where the tagged fish could recover from the handling.

During the initial stages of the project, a small number of fish were held in a 1.2 X 1.2 X 2.4 m holding pen for 0.6 to 9.1 h before being released. This permitted an evaluation of initial mortality rates of tagged fish and of regurgitation rates of tags. When we had determined that virtually all fish appeared to recover from the tagging and that few fish regurgitated tags, we stopped holding fish after tagging to eliminate any additional stress on the fish that might be associated with holding them.

Drift Nets: Along some sections of the river (i.e., near the sawmill at Gitwinksihlkw and near Gitlakdamix (Old Aiyansh, Fig. 2) it was more efficient to capture fish by drifting than by using stationary nets. The same nets were used for drift fishing and for sets. The net was set so that it would form a slight bow with the ends of the net being farther downstream than the middle. The net was allowed to drift downstream with one person holding one end of the net. When a fish entered the net, the net was retrieved. On several occasions two and occasionally three fish became entangled before the net could be recovered. The fish were lifted into the boat one at a time, removed from the net, and placed into the canvas holding pen. They were then handled as above for set nets.

Fishwheels: Large wooden fishwheels, similar to those used on the Yukon and Taku rivers (Meehan 1961; Donaldson and Cramer 1971; Milligan et al. 1985; McGregor et al. 1991), were used to capture salmon moving upstream and monitor the timing and relative numbers of anadromous fish species and stocks entering the Nass River. They are an ideal method of obtaining fish for tagging studies because fish are rarely injured during capture. In addition, they fish constantly and, therefore, provide a rate of capture that can be correlated with the numbers of fish moving through an area. Link et al. (1996) provide a complete description of the fishwheels and their use during 1992 on the Nass River.

## Tagging Effort

The effort expended to capture fish varied due to water level changes, weather conditions and other duties. Table 2 summarizes the fishing effort using nets. Daily net fishing effort for specific sites are provided in Appendix Table A-1. Daily summaries of the hours fished by fishwheels are presented in Appendix A Table A-2 and Link et al. (1996) describe the fishing effort by the fishwheels.

The area that was fished changed during the season because of changes in chinook salmon distribution. Initially we attempted to capture fish using nets at Grease Harbour above the main in-river net fishery (Fig. 2). We reduced our effort with nets when the first fishwheel began to fish on 5 June near Gitwinksihlkw (Canyon City). Initial fishwheel catches were low, so capture efforts were augmented using nets near Gitwinksihlkw from 912 June. On 15 June it became apparent, through the catch monitoring program, that fish were holding in the lower part of the river (see week of 6-12 June, Table 6 in English and Bocking (1993). From 16-23 June our tagging efforts focused on the lower river, primarily at Sandy River (Fig. 2), in order to increase the number of fish that were being tagged. Starting 24 June the fishwheels started to catch chinook at a rate of more than $10 / \mathrm{d}$ so we
stopped using nets except for a major effort on 26 June and brief tagging episodes during late June and early July.

We attempted to radio tag all healthy large ( $>72 \mathrm{~cm}$ long) chinook that were captured prior to 10 July when 338 of 400 radio tags had been applied. Some fish greater than 72 cm could not be radio-tagged because their stomach was too small to hold the radio tag without applying pressure to the back of the stomach. After 10 July, we limited radio tagging to large silvery-bright chinook caught to ensure that we would have sufficient radio tags to mark later run fish. We assumed that silvery-bright fish were new arrivals in the river. Another consideration was that our radio-tag data suggested that some fish were remaining in the lower river and were moving up and down the river past our radio-tagging sites. To avoid tagging these lingering fish at a higher rate than other fish, we decided to tag only new fish that were entering the river.

## Radio-tagging Procedures

Two slightly different handling procedures were used depending on the method of capture of the fish. Chinook salmon that were caught in nets were removed from the canvas holding tank and placed in a $30-\mathrm{cm}$ long sleeve that was suspended from a rigid pole resting on an aluminum frame. Fish caught in the fishwheels were removed from the holding pens with a dip net and placed in a V-shaped trough filled with water. Fish were not anaesthetized because some chinook were likely to be caught by the in-river net fishery or by sport fisherman and the effects of the available anaesthetics on the edibility of the fish are unknown. Processing included tagging the fish with an operculum tag, measuring the fish (nose-fork length), noting the presence of scars and marks and placing a radio tag down the throat of the fish and into the stomach with the antenna protruding from the corner of its mouth. The antenna was bent at the corner of the mouth so that the protruding part trailed along the side of the fish. The operculum tag number and the frequency and coded signal of the radio tag were recorded for each individual fish. The processing time (i.e., from removal from the holding tank to release) of each individual fish generally took less than thirty seconds and very rarely took more than two minutes.

The radio tag was the LOTEK model CFRT-7A digitally coded tag. This tag had a $180-\mathrm{d}$ life and was 16 mm in diameter, 80 mm long and weighed 44 grams in air. Ten different frequencies (149.520-149.700) each containing up to 50 different digital codes were used to distinguish between 400 radio tags purchased for this study. Tags to be applied to fish were selected so that different codes, and not more than a few tags on each frequency, were applied to fish caught on the same date. This precaution was taken to increase the detection efficiency of the receivers if fish captured at the same time or place remained together.

## Spaghetti Tagging

Chinook salmon captured in the fishwheels that were not required for the radiotagging program were tagged with regular type spaghetti tags (FT-4 spaghetti tag, Floy Tag \& Manufacturing Inc., Seattle, Washington, USA). The tagging procedures were similar to those described above for radio tagging and are described in more detail in Link et al. (1996). A total of 74 spaghetti tags were applied to chinook salmon (Table A-2).

## Tracking Methods

We determined the movements of radio-tagged fish using data collected from tracking surveys conducted from boats, trucks, helicopters and on foot. In addition, we set up fixedstation receivers that automatically detected and recorded radio-tagged fish that passed them. The tracking effort by each of these methods is summarized in Table 3.

Radio-tag Receivers: The radio-tag receiver used during this study was the SRX_400 built by LOTEK Engineering Inc. of Newmarket, Ontario, with their CODE_LOG version W16 data processing and storage program. The radio tag that was used could be detected at 1 km from ground level if the fish was in $4-5 \mathrm{~m}$ of water and farther if the tag was in shallower water or the antenna was higher. When flying at 500 m above ground level (AGL) we were able to pick up transmitters on fish in shallow water ( $1-3 \mathrm{~m}$ ) from $8-10 \mathrm{~km}$.

During tracking surveys the receiver scanned each frequency (channel) for 6 s during which time one to two pulses would be transmitted by a tag (the pulses are 5 s apart). The receiver then searched the next frequency. If a signal was received, the receiver decoded the signal, reported the tag code and signal strength and stored the data in internal memory. As many as $12-15$ different fish can be recorded on the same frequency during the same scan cycle ( 6 s ) so that the probability of a fish not being detected is low if only a few fish are present on a single frequency. The probability of missing a signal increases with the number of tags being detected on the same frequency at the same time. If 12 fish were on the same frequency in the same area, there is a high probability that one or more of these 12 might not be identified. The receivers, fitted with a single antenna, could scan ten frequencies and decode over 100 different radio-tagged fish within a 60 second period. During aerial tracking surveys we optimized tag detection and recording by varying our altitude and speed.

Telemetry data were automatically stored in an internal memory in the receiver and were transferred to a computer file on a portable computer whenever a survey was completed or a fixed station was visited. The data stored for each signal received by the receiver included the following:

1. date;
2. time ( $\mathrm{h} / \mathrm{min} / \mathrm{s}$ );
3. channel or frequency;
4. power level of signal;
5. antenna (if greater than one antenna was hooked up to the receiver);
6. signal code; and
7. code discrimination (variation from the actual code; this was used to distinguish false signals from fish).

Fixed Stations: Eight fixed-station (FS) receivers were established at strategic locations to automatically monitor the timing and the identities of fish moving up the Nass River (Fig. 1). The location of sites was selected to: 1) monitor fish entering known spawning systems (FS3 at the Cranberry River junction, FS2 at the Kiteen River junction, FS7 at the Damdochax Creek junction, FS9 at the Bell-Irving River junction); 2) monitor systems that might have spawning runs that have not been previously documented (FS8 at the White River junction); or 3) bracket rivers that might have spawning populations of chinook salmon (FS1 above Grease Harbour, FS5 at Sanskisoot Creek, FS6 at Sallysout Creek).

Each fixed-station consisted of one, two or three antennas and the SRX_400 receiver which was powered by a $12-\mathrm{V}$ deep discharge (RV) battery. The battery and receiver were enclosed in a weather-proof container and could operate for $2-3 \mathrm{wk}$ without servicing. We checked the operation of each station, replaced the $12-\mathrm{V}$ battery and downloaded the data from the receiver once every 2 wk except during the peak of the run when we checked stations every 3-4 d (lower river) or 7 d (upper river). The more frequent visits were required to download data from the receivers internal memory which would have become full when many radio-tagged fish were present near the stations.

Multiple antennas ( 2 or 3 ) were used to determine the direction of travel of fish near fixed-stations that were established at the junctions of tributaries. Antennas were arranged so that number one antenna pointed up the Nass River, number two pointed up the tributary and number three, if present, pointed down the Nass River. The antennas were all connected to a peripheral device that controls and alters the scanning sequence of the receiver. It scans on a combined signal from all antennas. When a signal is received, the receiver records the data as being on antenna 0 and then switches sequentially to each antenna to determine which antenna is recording the tag. The time spent on a frequency, if a fish is present, is 24 s when the station has three antennas. If fish were recorded on all 10 frequencies, the scanner would take 4 min to return to the initial frequency; whereas, if no fish were detected, the scanner would take 1 min to return to the initial frequency. Fish passing the fixed stations were within receiving range of the antenna for at least $5-10 \mathrm{~min}$. Therefore, failure to identify a passing fish was very unlikely, and most fish were recorded at least 7 times (and most often a few hundred times) before they passed a fixed station. This repetitive recording of individual fish permitted confirmation of signals as being from passing fish.

Tracking by fixed stations provided the most continuous coverage of fish movements of the five tracking methods that were used. A total of 736 site days of monitoring was obtained from the fixed stations (Table 3). The first station was set up near Grease Harbour (FS1) on 24 May and the last two stations were removed on 25 September. The data from
the fixed stations provided precise data on the arrival and departure times and dates of fish past each station. These data could not have been obtained using the other tracking methods.

Aerial Tracking: Aerial tracking was conducted from a Bell 206 helicopter with a single Yagi antenna attached to the cargo skid on the right side of the aircraft. The aircraft flew along the river and its tributaries at $40-130 \mathrm{~km} / \mathrm{h}$ and at $30-300 \mathrm{~m}$ AGL. Whenever large numbers of radio-tagged fish were located the helicopter reduced speed or hovered to permit identification of the position of the fish and to permit the receiver to scan the other frequencies. The location of each fish was determined in real time by a Global Positioning System (GPS) receiver and data logger and the approximate position and the identity of each fish that was located were recorded manually on data sheets, as well as automatically in the internal memories of the receiver and GPS. The position of the fish was later confirmed by comparing signal strengths and the GPS positions that were machine-recorded. During some surveys two receivers were operated on different frequencies so that the probability of passing a fish without recording it was reduced. Aerial tracking was conducted whenever we flew, but during aerial surveys dedicated to tracking, we maintained an air speed of 40-60 $\mathrm{km} / \mathrm{h}$ and an altitude of 150 m to maximize our chances of recording each fish present.

Aerial tracking was most valuable to document the location and residence times of chinook after they had entered their spawning streams (Table 3). A list of aerial telemetry surveys conducted during the mid-July to late September period can be found in Appendix B.

Boat Tracking: The section of the lower Nass River from 5 km above Grease Harbour to Fishery Bay (Fig. 2) was tracked by boat once each week from late June to midSeptember.

Boat-based tracking was conducted from a $5.8-\mathrm{m}$ long welded aluminum boat that was powered by an outboard motor with a jet propulsion unit. The jet powered boat was required to access the numerous shallow side channels that were used by fish. The tracking antenna (4-element Yagi) was mounted at the top of a 3-m long aluminum pole that stood inside a PVC pipe mounted along the side of the console. The PVC pipe isolated the antenna from direct contact with the boat and facilitated its removal during transit or when tracking was not being conducted.

All boat surveys were conducted from upstream to downstream. The boat motor was turned off and the boat drifted while tracking was conducted because the outboard motor created electronic noise that interfered with signal reception by the receiver. When fish were present in an area, the boat was stopped or permitted to drift through that area until all fish were recorded. The boat was then moved $1-2 \mathrm{~km}$ downstream and the procedure was repeated. From late June to late July, when large numbers of fish were present in the areas tracked from the boat, we drifted from Grease Harbour (FS1) to Fishery Bay (Fig. 2).

As above, all radio-tag signals were recorded in the receiver and all position information was determined by and stored in the GPS. Fish identities, time, and approximate positions were also recorded manually on data sheets.

Truck and Foot Tracking: Tracking was also conducted from a truck and on foot on an opportunistic basis. Most foot surveys were conducted during ground-based counts of chinook salmon along the Damdochax, Bell-Irving and Kwinageese systems, but foot surveys were also conducted on the Seaskinnish and Cranberry systems. Truck surveys were conducted of the Tseax River and mainstem Nass River near Gitwinksihlkw. A four-element Yagi antenna was used for both boat and truck surveys. A collapsible three-element antenna was used during foot surveys. Data recording procedures were identical to those described above.

## Data Processing

The data from each station or survey were screened for spurious signals using existing computer programs and were incorporated into the radio-tag database. Spurious signals were identified among the logged data by low signal strength and few or no repetitions. Using these criteria, personnel from the University of Idaho have been able to remove spurious signals from the raw data files without removing actual fish tag records (Ted Bjornn, pers. comm.).

The data (almost one million lines) were then converted into a Dbase format (Foxpro 2) and condensed to one record for each fish at each location on each day. Programs were written to identify implausible movements or positions, match survey times and locations with fish tracking records and summarize the data for presentation in tables and figures.

## ESCAPEMENT SURVEYS

## General Approach

The purpose of the escapement surveys was to count chinook salmon in a manner that would allow us to use the counts to estimate the chinook escapement to the Nass River and its tributaries. We designed the study to concentrate field survey effort on a few known, major chinook spawning areas, while remaining flexible about where to apply the remaining effort. By targeting the effort on the systems that historically contained large numbers of chinook salmon, the information that we gathered would allow us to estimate precisely a large proportion of the total Nass River chinook escapement. The remainder of the survey effort was to be allocated to surveying historically less abundant stocks and to any systems that the radio-telemetry information indicated were potentially important spawning areas.

The Damdochax, Kwinageese, Meziadin and Cranberry/Kiteen systems have historically contained the majority of the estimated spawning escapement of chinook salmon (Table 1). These systems were classified as major for the purposes of this study and were
visually surveyed from a helicopter at intervals of 4-13 d from early August to midSeptember. Ground surveys, a fishway, a weir and radio telemetry were also used to count fish in these systems.

By mid-August, the fixed-station radio receiver at the junction of the Bell-Irving and Nass rivers (FS9, Fig. 1) had identified that a substantial portion of the radio-tagged fish had entered the Bell-Irving River (approximately $25 \%$ of the 255 radio-tagged fish tracked to apparent destinations by that date). As a result, the Bell-Irving River was upgraded to a major spawning area and aerial and ground surveys were initiated in that system.

The remainder of the chinook spawning areas (minor systems) were surveyed less frequently using predominantly aerial visual surveys and aerial telemetry to count fish. The primary purpose of these surveys was to determine the distribution and abundance of radiotagged fish which were then used to estimate the escapement of chinook with a markrecapture method (see Analytical Techniques, below). The visual surveys also provided minimum estimates of the escapement. Occasionally ground surveys were conducted to verify or replace aerial surveys. At the start of each week beginning in early August a list of desirable surveys was compiled to determine if and when to survey minor systems. The priority of these surveys was defined using the following criteria (in descending order of importance):

1. the magnitude of the historical escapement (high escapement, high priority);
2. the number of radio tags determined to be in the area by fixed and mobile receivers (large number of tags, high priority);
3. the flight time required to survey the system, including the ferry time from base camp or from adjacent survey areas (little flight time required, high priority);
4. the abundance of fish and the degree to which spawning was complete. This was determined from previous surveys (high abundance, high priority; spawning near peak, high priority); and
5. the amount of potential spawning habitat. This was evaluated during other overflights (large amount of spawning habitat, high priority).

The number of surveys completed each week depended on the weather conditions, availability of aircraft and personnel, budget considerations and logistical constraints which included coordination with other studies.

Some systems were surveyed using several techniques. The variation among estimates obtained for the same system using these different techniques was used to evaluate the reliability of each technique for estimating chinook escapement on the Nass River.

## Survey Procedures

Aerial and ground surveys were used extensively to count chinook salmon in 1992 and ground surveys were used to examine carcasses and recover radio and spaghetti tags. These techniques are described in detail below.

Aerial surveys: All aerial surveys were conducted from a Bell 206B helicopter equipped with a rear bubble window. A single surveyor visually counted fish from a rear window seat of the aircraft; the same individual (Michael Link) was the observer throughout the entire field season. He has nine years of experience counting salmonids from helicopters, boats and on foot. The aircraft was turned or oriented so that the observer could see along the stream ahead of the aircraft. The direction of flight (upstream or downstream) was chosen to minimize glare and strong tail winds. Trainees were also present on most surveys, but their counts were not used for any analyses although they were compared to those of the primary observer as part of the training process. The helicopter flew $30-200 \mathrm{~m}$ above the water and at air speeds of $0-150 \mathrm{~km} / \mathrm{h}$. The initial survey speed was usually 100 $\mathrm{km} / \mathrm{h}$ and it was reduced when fish were encountered. The survey speed was then adjusted to allow the surveyor to comfortably and accurately count individual fish. Counts were usually conducted at air speeds of $10-60 \mathrm{~km} / \mathrm{h}$. Occasionally, groups of fish were too dense to count fish individually and group sizes had to be estimated. The number of fish in these groups was estimated by visually partitioning the group into strips containing approximately 10 fish and then counting the number of strips that comprised the group.

Each system was divided into reaches in order to stratify the counts. Boundaries of reaches were selected using both natural changes in the river (waterfalls, riffles, deep holes) and convenient landmarks (rock bluffs, bridges). Reach specific data were useful in monitoring upstream migration and comparing aerial and ground survey counts.

Live fish were categorized as either spawning or holding. Spawning fish were those fish that were on or within 5 m of redds. Fish that were not near redds, but showed obvious signs of advanced spawning condition, (i.e., worn and/or discoloured tails or fungus patches on their skin) were also categorized as spawning. All other live fish were assumed to be holding. Dead fish (carcasses) were not systematically enumerated during aerial surveys, but were recorded when time permitted. During aerial surveys, the time was usually recorded at the start and end of each reach. A GPS unit operated continuously during the surveys (see Aerial Tracking above) and the GPS position was occasionally used as a backup method to determine the location of the helicopter at a given time. This permitted us to assign counts to particular reaches even if the reach boundaries were not recorded during the survey. Summaries of numbers of fish that were spawning and holding in each reach were used to determine approximate locations of spawning areas and the timing for peak spawning activity.

Factors that might affect the ability of the surveyor to see or record fish (observer efficiency) were recorded on a survey form along with actual counts of fish by reach. Figure

D-1 shows the survey form used in the field and Table D-1 defines the codes that were used. Data recorded included: weather (cloud cover, precipitation and wind speed and direction); light conditions; water clarity, both airspeed and elevation (above the water of the survey aircrafts), direction of travel; water level (relative to previous surveys or to natural landmarks); and the names of the pilot and all surveyors. In addition, the surveyor kept notes on fish distribution, the degree to which overhanging vegetation interfered with counting, the aircraft speed when fish were being counted and the ability of the surveyor to concentrate. These data were recorded to provide information related to the potential biases in the aerial counts and to permit more accurate comparisons of the 1992 estimates with those from past and future surveys.

At the end of each survey, the surveyor attempted to estimate his efficiency (the percentage of fish present that were recorded). The estimate took into account all of the factors noted above and was subjective, but it was made to give an overall estimate of the reliability of the count that may not have been readily apparent from the description of the survey conditions.

Ground Surveys: Ground surveys were conducted to evaluate aerial counts and to examine carcasses of chinook salmon for radio, operculum and spaghetti tags (carcass counts). A crew of two or three surveyors walked alongside and through the stream to count live and dead fish. Small or dispersed groups of live fish were counted individually and classified as either spawning or holding. Dense groups of fish were estimated as described above for aerial counts. Ground survey counts were stratified into the same reaches as used during the most recent aerial survey of the area.

On two occasions, two surveyors used a 3 m rubber raft to conduct a float survey of Damdochax Creek. The same methods of counting and recording fish (as outlined above) were employed during float surveys. Carcasses were not encountered on the two float surveys.

During ground surveys, each carcass was examined for radio, operculum and spaghetti tags. Carcasses were counted and categorized as females, males ( $>50 \mathrm{~cm}$, nosefork length) or jacks (males $<50 \mathrm{~cm}$, nose-fork length). After carcasses were examined they were cut in two near the caudal peduncle to indicate that they had been examined and counted if they were encountered during later surveys. The processed carcasses were returned to the river bank because recent studies have shown that salmon carcasses may provide important nutrients for growth of young fish in salmon streams.

Carcasses of radio-tagged fish were examined for general physical condition, sex, spawning condition and the age of the carcass. The stomachs and digestive tracts of several fresh carcasses were examined to determine if radio-tag placement or retention resulted in any physical injury. Any physical abnormalities or injuries were recorded and these notes were compared to notes taken at the time of tagging to determine if they occurred after tagging. The spawning status of females was assessed by examining the gonads in carcasses;
they were recorded as fully spawned if the gonads were completely empty, partially spawned if some eggs remained and non spawners if the gonads were intact and all eggs appeared to be retained. The age of the carcass was estimated using the degree of deterioration of the carcass. The following characteristics were used to estimate the number of days (in parenthesis) since the fish died:

1. bright red gills, little or no rigor mortis (1 d);
2. gills dull red with white patches, carcass stiff or beginning to loosen, flesh firm (2-3 d);
3. gills white, fungus layer on skin, flesh very soft (4-5 d); and
4. gills white/grey, heavy covering of fungus, flesh mushy (6-7 d).

The rate of deterioration varied slightly among systems and throughout the period of the spawning run so that ages determined for particular systems or particular periods varied slightly from the above criteria. The estimated ages based on the above criteria varied by as much as 2 d . Carcasses that had been cut in half during the previous survey provided a basis for estimating the age of fish that had died between survey periods. These cut carcasses gave an indication of the rate of carcass deterioration that was specific to that time and that system. The date that a radio-tagged fish died was used in conjunction with the date that the fish entered that system to provide an estimate of its total residence time for the Area-Under-the-Curve (AUC) method of estimating escapement (see Analytical Techniques below).

## Systems Surveyed

As mentioned previously, different methods and different amounts of effort were used to estimate chinook escapement to different tributaries or stocks of the Nass River system during 1992. This section describes the methods used to estimate escapement for each stock (Table 4). A summary of the quantity, timing and distribution of stream survey efforts is presented in Table 5.

Damdochax Creek: Both aerial and ground survey counts were used to obtain point estimates of the abundance of live fish and ground surveys were conducted to examine carcasses for the presence of radio, spaghetti and operculum tags. The live counts were converted into an escapement estimate using the AUC estimation technique. Carcass recovery data were combined with the number of radio-tagged chinook entering the creek to compute an independent mark-recapture estimate (Table 4; see Analytical Techniques, below).

Damdochax Creek was surveyed by helicopter at intervals of 4-7 d from 4 August to 10 September 1992. Visual counts of chinook salmon were obtained from seven surveys conducted between the confluence of Damdochax Creek at the Nass River and the outlet of Damdochax Lake (Fig. 3). Four Damdochax tributaries: Sansixmor, Slowmaldo, Yaza and Wiminasik creeks were also surveyed by helicopter on one or two occasions during the suspected peak of spawning at these locations (Table D-2).

Five ground surveys were conducted of Damdochax Creek between the outlet of Damdochax Lake and the confluence of Slowmaldo Creek (reaches 4 and 5, Fig. 3) from 10 August to 16 September 1992 (Table 5). This section of the stream contained the majority of spawning activity and was difficult to survey accurately from the air. Large numbers of fish were present in a relatively short stretch of stream. The stream channels were narrow, the water was turbulent and the helicopter frightened some fish both ahead of and behind the helicopter. It was difficult to count fish moving downstream among previously counted fish and to determine whether upstream moving fish were counted twice. Fish were difficult to see in turbulent water and other fish were under stream banks or tree branches where they could not be seen from the air. Consequently, the ground surveys conducted in these reaches obtained more accurate counts of chinook than could be obtained from aerial surveys.

For reaches 1-3, which are between Slowmaldo Creek and the Nass River, the aerial count was the best estimate. Initially, this section was surveyed on foot and from a raft. These survey techniques were unsuitable for counting fish in this area. This reach is characterized by wide (up to 20 m ), slow moving channels and deep holes. Chinook were difficult to see when they were in deep water and more than 8 m to the side of the surveyor.

We estimated the total number of live fish in Damdochax Creek on each survey date as the sum of the ground counts for reaches 4 and 5 and the aerial counts for reaches 1-3 (i.e., we assumed an observer efficiency of $100 \%$ when we used the best survey technique).

Cranberry/Kiteen Rivers: The escapement to the Cranberry and Kiteen rivers was estimated using a mark-recapture method based on the number of radio-tagged fish tracked to these rivers and the overall radio-tagging rate for chinook in the Nass River system (see Analytical Techniques).

Initially, aerial surveys were conducted of the Cranberry River to count live fish. The counts were to be used to estimate the escapement using the AUC method. However, the Cranberry River was too muddy and deep to make accurate counts from the air. Because of the poor survey conditions, we reduced our survey effort, but we continued the surveys to determine the number of radio-tagged fish present and to obtain minimum counts of the numbers of fish present during each survey.

The Cranberry River was surveyed by helicopter at intervals of 6-9 d from 26 July to 2 September 1992 (Tables 5, D-2). Visual counts of chinook salmon were obtained from four surveys conducted on 13,19 and 25 August and 2 September. The river was usually surveyed from its confluence with the Nass River to Weber Creek (approximately 60 km upstream, Fig. 4). For more detailed descriptions of the sections of the river surveyed on each date see Appendix Table D-2.

The Kiteen River was surveyed by helicopter on 13 and 19 August to determine the number of radio-tagged fish in the river and to obtain a minimum estimate of the number of chinook present. The mainstem Kiteen River was surveyed from its confluence with the

Cranberry River to Cohead Creek (approximately 38 km upstream, Fig. 4). The lower 8 km of Stenstrom Creek, a tributary of the Kiteen River, was surveyed on 19 August.

Kwinageese River: The escapement to the Kwinageese River was estimated using the mark-recapture method, the number of radio-tagged chinook in the Kwinageese system, and the mark rate obtained from examining carcasses in that system.

A wooden fish weir was also used to enumerate chinook salmon returning to the upper Kwinageese River. In addition, aerial and ground surveys were conducted to estimate the minimum number of fish spawning above and below the weir and ground surveys were conducted to examine carcasses for tags.

The weir was located on the Kwinageese River 4 km downstream of Fred Wright Lake (Fig. 1); it was operated from 17 July to 23 September 1992. The purpose of the weir was to enumerate migrating sockeye and chinook salmon. The weir was framed with 5 X 10 cm lumber ( $2^{\prime \prime} \mathrm{X} 4^{\prime \prime}$ ) and covered with 2.5 cm X 2.5 cm (1") wire mesh. A trap (pen) was installed along the weir near the west bank of the river. Initially, fish were trapped, sampled and released upstream. On 30 July, an electronic tunnel counter was installed on the upstream end of the trap. This counter was used for most of the remainder of the project to estimate the number of fish passing the weir. Chinook were reluctant to pass through the counter. Therefore, when build-ups of chinook were observed below the weir, fish were allowed to pass (bypass counts) by removing one $1.2 \times 1.2 \mathrm{~m}$ panel from the centre of the weir. Fish were visually counted as they passed.

Periodic visual counts (index counts) were made of the fish using the tunnel counter in order to determine the proportions of chinook and sockeye that passed through the tunnel counter and to derive a correction factor to adjust machine counts to actual counts. The index counts were conducted for periods of 1 to 4 h at intervals of 1 to 4 d . The time of day that index counts were made was varied to include all hours of the day. The number of chinook using the tunnel counter was then estimated based on the corrected electronic counter tally and the estimated proportion of chinook using the counter. The proportions used to estimate the daily chinook passage were determined by pooling the results from index counts conducted over 7 d . To estimate the number of chinook using the counter each day within the stratum, the average proportion from the 7-d period was multiplied by the corrected electronic counter tally. The biases associated with these estimates are discussed later with the presentation of the escapement estimate.

The Kwinageese River was surveyed by helicopter from its confluence with the Nass River to Fred Wright Lake at intervals of 4-13 d from 4 August to 15 September 1992. Radio tracking was conducted on 11 aerial surveys and visual counts of chinook were obtained from six of these surveys (Table 5). Shanalope Creek, a tributary of the Kwinageese River, was surveyed by helicopter on 18 and 26 August and 2 September. Additional information on the aerial surveys can be found in Table D-2.

Three complete ground surveys were conducted along the stretch of the Kwinageese River between the weir and Fred Wright Lake from 3 to 15 September and one partial ground survey was conducted below the weir on 22 August to count live fish and to examine carcasses for the presence of tags. In addition, the weir crew examined carcasses opportunistically while conducting sockeye studies (Table D-4). Chinook carcasses that drifted up against the weir were also examined for the presence of radio tags.

Meziadin River: The escapement to Meziadin River was estimated using the markrecapture method, the number of radio-tagged fish tracked into Meziadin River, and the overall Nass River mark rate. The Meziadin fishway count provided a minimum estimate of the number of chinook salmon spawning above the fishway.

The Meziadin fishway is a vertical slot fishway. It was built in 1964 and its location, structure and operation are described in Southgate et al. (1988). Its primary purpose is to allow returning salmon to bypass a partially impassable series of waterfalls.

The fishway was operated by the Department of Fisheries and Oceans from 16 July to 5 October 1992; during this period, it was closed to fish passage when observers were not present so that all fish passing through the fishway could be counted. Salmonids passing through the fishway were counted as they swam through one of two counting chutes. A glass-bottom box was floated on the surface of the water inside the chute to provide good visibility into the water. All passage was done during daylight hours and the duration of the periods of passage depended on the numbers of fish that were present in the fishway.

Chinook salmon were identified as either adults or jacks and enumerated. Adult chinook were distinguished from other species (sockeye, coho and pink salmon and steelhead trout) and from chinook jacks ( $<50 \mathrm{~cm}$ ) primarily by their size. Chinook jacks were distinguished from other species by the number and patterns of their spots. Radio-tagged and spaghetti-tagged chinook salmon were enumerated and allowed to pass through the counting area.

A total of 13 radio-telemetry tracking flights were conducted over the Meziadin River at intervals of 1-9 d from 26 July to 24 September (Table 5). Some of these (2) were overflights where we did not systematically survey Meziadin River, but they provided data on an unknown fraction of the fish present at the time of the overflight. Visual counts were conducted from the helicopter on the 4 and 18 August and 6 September surveys.

Bell-Irving River: The escapement to the entire Bell-Irving River system was estimated using a mark-recapture estimate based on the number of radio-tagged fish tracked into the Bell-Irving River and the overall radio-tagging rate for chinook salmon in the Nass River system. To estimate the contributions of individual tributaries of the Bell-Irving River to the overall Bell-Irving escapement, separate mark-recapture estimates were also derived for all tributaries where radio-tagged fish were found (however, we did not survey all tributaries of the Bell-Irving River). In addition, the escapement contributions by the
tributaries that were surveyed are minimum estimates because some fish that were recorded in the main river may have entered tributaries before, between or after our few surveys of the system.

A fixed-station receiver with three directional antennas was placed at the junction of the Nass and Bell-Irving rivers (FS9, Fig. 1) to record all radio-tagged fish passing this location and to distinguish fish entering the Bell-Irving River from those continuing up the Nass River. In addition, aerial tracking, aerial visual surveys and ground surveys were conducted on the Bell-Irving River and selected tributaries to determine the distribution of the tagged fish and to obtain minimum estimates of the escapement to the major spawning areas within the watershed.

The Bell-Irving system was surveyed by helicopter on 18 and 20 August and 5 and 6 September. Ground surveys were conducted on 23 and 29 August and 5 and 6 September. For details of these surveys see Appendix D.

Upper Nass Mainstem: The escapement to the upper Nass River (above Cranberry River) mainstem and minor tributaries was estimated using the mark-recapture method and was based on the number of radio-tagged fish recorded along the mainstem of the upper Nass River and the overall radio-tagging rate for chinook in the Nass River system. This estimate accounted for small numbers of chinook salmon that were spread throughout this part of the river system and that spawned either on or near the main river. Only a few of the many smaller tributaries that are included in this overall estimate were actually surveyed; Muskaboo, Kotsinta and Saladamis creeks were the tributaries surveyed.

Other sections of the mainstem and adjacent tributaries were surveyed opportunistically by helicopter from 13 July to 24 September. In addition, movements of some radio-tagged fish were monitored by the fixed stations.

Muskaboo Creek: The escapement to Muskaboo Creek was estimated using the count of fish observed during a single aerial survey of Muskaboo Creek on 17 August. The creek was visually surveyed and concurrently surveyed for radio tags from its headwaters to the Nass River (approximately 25 km ).

Kotsinta Creek: The escapement to Kotsinta Creek was estimated using the count from a single aerial survey of Kotsinta Creek on 3 September. The creek was surveyed from its confluence at the Nass River to a large waterfall approximately 5 km upstream.

Saladamis Creek: A single aerial survey of Saladamis Creek was conducted on 27 August. The creek was surveyed from its confluence with the Nass River to approximately 4 km upstream.

Lower Nass Mainstem: The escapement to the lower Nass River (below Cranberry River) mainstem was estimated using the mark-recapture method and was based on the
number of radio-tagged fish recorded along the mainstem of the lower Nass River and the overall radio-tagging rate for chinook in the Nass River system. This estimate may include a few fish that spawned in small tributaries adjacent to the Nass River.

Sections of the mainstem of the lower Nass River were surveyed opportunistically by helicopter from 13 July to 24 September and the section from Grease Harbour to Fishery Bay (Fig. 2) was surveyed weekly by boat from 13 July to 15 September.

Lower Nass Tributaries: The escapement to the lower Nass River (below Cranberry River) tributaries was estimated using the mark-recapture method and was based on the number of radio-tagged fish recorded in all of the lower Nass River tributaries and the overall radio-tagging rate for chinook in the Nass River system. This estimate may include a few fish that spawned on the mainstem Nass River, but that moved into a tributary for a short period of time and were tracked while in the tributary.

Estimates for individual tributaries were also made using the mark-recapture method, but we have less confidence in the individual estimates than in the overall estimate because the tagging effort of lower river fish appears to have been over-represented among the early arriving fish (primarily Seaskinnish and Tchitin systems) and under-represented among the late arriving fish (Tseax River and Slough). The recapture rate in the tributaries is also low and the estimates for each tributary are, therefore, less reliable than the pooled estimates.

Tchitin River: The escapement to the Tchitin River was estimated using a markrecapture estimate based on the number of radio-tagged fish tracked into the Tchitin River and the overall radio-tagging rate for chinook in the Nass River system. The Tchitin River was surveyed by helicopter on 4 and 18 August from its confluence with the Nass River to approximately 18 km upstream. We systematically searched for radio-tagged fish and made visual counts on both surveys. In addition, radio-tagged fish were recorded during numerous ferry flights from Nass Camp to Meziadin Lake and during surveys of the mainstem of the Nass River near the Tchitin River.

Seaskinnish Creek: The escapement to the Seaskinnish Creek was estimated using a mark-recapture estimate based on the number of radio-tagged fish tracked into the Seaskinnish Creek and the overall radio-tagging rate for chinook in the Nass River system. It was also estimated indirectly as part of the entire lower river. We conducted six aerial telemetry surveys of Seaskinnish Creek from 19 August to 24 September, and an aerial count was also made during the 19 August survey. A foot survey was conducted on 28 August of the lower and middle section of the river as far upstream as the falls.

Tseax River and Slough: The escapement to the Tseax system was estimated using the mark-recapture method, but the last survey was conducted too early to detect some of the spawning fish that may have entered this system after our surveys were terminated. We conducted five aerial telemetry surveys of Tseax River and Slough from 14 August to 24

September. Peak spawning was in early October. We attempted to visually count fish during the 19 August survey, but turbid water made enumeration from the air ineffective.

Other Lower Nass Tributaries: Single aerial surveys were conducted of Kwinatahl, Zolzap, Anudol and Ksedin systems on 14 August. The delta of Anudol Creek was surveyed a second time by helicopter on 26 August. Shumal Creek was surveyed from the confluence of Nass River to 12 km up the creek on 10 September. Visual and telemetry surveys were conducted concurrently on all five systems.

Other Systems: The fish entering several of the tributaries on the lower Nass River would not have been radio tagged, or would have been tagged at a rate that was lower than their contributions to the Nass River escapement, because they were below the tagging sites. Two of these rivers, the Ishkeenickh and Kincolith rivers, were surveyed. Our escapement estimates for these rivers were obtained by dividing the actual counts by the estimate of observer efficiency. No escapement estimates could be made for the other systems.

Ishkeenickh River: The Ishkeenickh River enters the Nass River 25-30 km downstream of the closest radio-tagging site at Sandy River (Fig. 2). Ishkeenickh River fish were not subjected to the same tagging rate (i.e., few or no Ishkeenickh fish would have passed our tagging sites) as were the stocks that spawned farther up the Nass River. Therefore, we were unable to calculate a mark-recapture estimate based on our radio-tag data.

The escapement to the Ishkeenickh River was estimated using a single aerial count of live fish obtained on 14 August. The river was surveyed from its confluence with the Nass River to approximately 55 km upstream. Telemetry was conducted concurrently with the aerial count during the 14 August survey.

Kincolith River: The Kincolith River flows into the Portland Inlet 40 km downstream of the closest radio-tagging site (Fig. 2); therefore, for the reasons stated above, we were not able to use our radio-tag data to calculate escapement to this system. The escapement to the Kincolith River was estimated using a single aerial count of live fish obtained on 14 August. The river was surveyed from its mouth to approximately 60 km upstream. Telemetry was conducted concurrently with this survey.

## ANALYTICAL TECHNIQUES

The analytical techniques used to estimate the Nass River chinook salmon escapement based on the data gathered during field surveys are outlined below. Table 4 summarizes which of these techniques were used to determine the escapement to each of the tributaries of the Nass River.

## AUC Estimation

We estimated the escapement to Damdochax Creek using the area-under-the-curve (AUC) technique. The AUC technique is a method used to convert periodic counts of mature salmon into an estimate of the total escapement (Ames and Phinney 1977; English et al. 1992). Point estimates of fish abundance over time are connected by a contour line to form an escapement curve. The escapement estimate is obtained by dividing the area under the escapement curve ( $a u c$ ) by the stream residence time $(r t)$. The stream residence time is the average period of time that fish spend in the survey area.

Escapement Curve: In this study, we used counts of live fish obtained from periodic aerial and ground survey counts to estimate the number of live fish in Damdochax Creek. Unless otherwise noted, we estimated the total number of live fish as the sum of the ground counts for the upper two reaches and the aerial counts for the lower three reaches.

The point estimates of the numbers of live fish (survey counts) were joined to form the escapement curve. The curve was temporally bounded by the date that fish first entered the survey area and the date that no live fish remained in the area. These two dates were estimated by extrapolating the ascending and descending slopes of the escapement curve beyond the first and last survey dates, respectively. The first two and last two data points were used to calculate the slopes of the ascending and descending slopes. For Damdochax Creek, the curve was extended 5 d before the first survey date and 5 d after the last survey date.

Residence Time: We used two methods to estimate the stream residence time ( $r t$ ). The first method uses data from radio-tagged fish that were recovered during carcass surveys. The dates when these tagged fish entered Damdochax Creek were recorded by a fixed-station receiver (FS7, Fig. 3) positioned at the entrance to the stream. The dates that the recovered fish died were estimated during the carcass examinations that were conducted during ground surveys. The residence time for each fish was the difference between these two dates and $r t l$ was the mean residence time for all fish. In the second method, stream residence time ( $r t 2$ ) was estimated as the interval between peak live and peak dead counts. Both techniques are reviewed in Perrin and Irvine (1990).

AUC Escapement Estimate: The area under the escapement curve (auc) was calculated using the equation from English et al. (1992):

$$
\begin{equation*}
a u c=0.5 \cdot \sum_{i=2}^{n}\left(t_{i}-t_{i-1}\right) \cdot\left(p_{i}+p_{i-1}\right) \tag{1}
\end{equation*}
$$

where $t_{i}$ is the number of days since the first fish entered the survey area, $n-2$ is number of surveys, and $p_{i}$ is the number of live fish present in the stream on the $i^{\text {th }}$ day.

The AUC escapement estimate was obtained using the equation:

$$
\begin{equation*}
E S C=a u c \cdot r t^{-1} \tag{2}
\end{equation*}
$$

where $r t$ is the stream residence time derived from the $r t 1$ or $r t 2$ method described above.
Originally, it was our intent to obtain AUC estimates for the Cranberry River. Unfortunately the Cranberry River was very turbid during most of the 1992 spawning period and we could not obtain accurate counts of live fish. The estimates of observer efficiency at the end of each survey ranged from unknown-but-low to $30-80 \%$ (Table D-2). On surveys, conducted on 25 August and 2 September, the surveyor was so uncertain of his efficiency that he could not quantify it.

The aerial counts of fish in the Cranberry River did, however, allow us an opportunity to independently verify the "reasonableness" of the adjusted Petersen estimate derived from the radio-tag information. To do this, we made the assumptions that fish in the Cranberry River had the same residence time as did the fish in Damdochax Creek, and then calculated the observer efficiency that would have been necessary on the aerial surveys in order to derive an AUC estimate comparable to the adjusted Petersen estimate.

The surveyor was confident that the observer efficiency on all surveys was less than $100 \%$ because the visibility into the water was poor. Thus, we can assume that not all fish were seen. If the calculated observer efficiency (using the method described above) was higher than $100 \%$, this exercise would provide evidence that the adjusted Petersen estimate was an underestimate.

If the calculated observer efficiency was similar to what the surveyor had estimated, it would provide some additional confidence in both methods. If the calculated observer efficiency was much lower than the surveyor had estimated, the exercise would suggest either that some of the assumptions about fish distribution or residence times were wrong or that the adjusted Petersen estimate was an overestimate.

## Mark/Recapture Estimation

Chinook escapement for the entire Nass River system and individual tributaries, where intensive carcass surveys were conducted, were estimated using the adjusted Petersen estimate from Ricker (1975):

$$
\begin{equation*}
N=\frac{(M+1) \cdot(C+1)}{R+1} \tag{3}
\end{equation*}
$$

where $N$ is the population estimate, $M$ is the number of tagged fish in the river system as determined by radio telemetry surveys and fixed-station receivers, $C$ is the number of fish examined for tags during ground surveys in that system, and $R$ is the number of tags recovered in the sample $C$.

For tributaries that were not intensively surveyed to determine tag rates, we prorated the remainder of the total Nass escapement estimate (i.e., total escapement estimate minus tributary specific estimates) using the portion of the total radio tags tracked to each tributary.

Where appropriate, the $95 \%$ confidence limits for the Petersen estimate were calculated by replacing the number of recoveries ( R ) in formula (1) with the fiducial limits taken from the Poisson distribution (p 79, Ricker 1975). The fiducial limits of R were obtained by substituting R for $\chi$ in Appendix II of Ricker ( p 343 , 1975).

Stratification of Data: Stratification of population estimates by stock and sub-stock (e.g., by tributary or by age and/or sex within tributaries) components can often reduce the potential for systematic biases (Bocking et al. 1991). Fish from different stocks may have passed our tagging sites at different times and consequently fish from different stocks may have been tagged at different rates. The data on the timing of movements of fish from different stocks suggest that this should not have been a serious source of bias for the stocks that moved up the river beyond Grease Harbour (see RESULTS - Upstream Movements).

Nevertheless, we minimized these biases by analyzing the data from different stocks separately whenever we had more than five tag recoveries during carcass examinations in a system.

The problem of accurately enumerating chinook jacks was largely avoided by the size limitations associated with the radio tagging. Jacks were defined as those chinook less than 50 cm in fork-length. Since radio tags could not be applied to any chinook less than 72 cm , no jacks were tagged. Consequently, our population estimates only represent adult chinook.

We were unable to stratify by sex because the sex of many of the tagged individuals was uncertain. It was difficult to determine the sex of the tagged fish at the lower-river tagging sites where the fish had only recently left the ocean. Fish were often silver-bright and secondary sexual characteristics, like a kype or a ridged back, had not developed.

Mark-Recapture Assumptions: Biases in Petersen estimates can occur when the principal assumptions of the estimation procedure are violated (p. 81-82, Ricker 1975). The relevant assumptions are:

1. The marked fish suffer the same natural and fishing mortality as the unmarked fish;
2. The marked fish are equally vulnerable to the recapture technique as are the unmarked fish;
3. The marked fish do not lose their marks;
4. The marks are applied randomly over the entire run; and/or marked fish become randomly mixed with the unmarked fish; and/or the recovery effort is proportional to the number of fish present in different reaches of the system; and
5. All marks are recognized and reported on recovery.

Our assessment of the validity of each of these assumptions is presented below (see DISCUSSION).

## RESULTS

## RADIO TAGGING

## Tagging Success

Radio tags were placed in 360 chinook salmon during 1992. Tagging was conducted over a period of 3.5 months from 15 May to 29 August (Appendix A) but $89 \%$ of the fish (320) were tagged during a 5 -w period from 13 June to 17 July 1992 (Table 6). Thirteen chinook were tagged in the upper section of the Upper Stratum (Greenville bridge to Grease Harbour) of the Nisga'a fishery area during May using a combination of set and drift nets to capture fish. Drift fishing was the most efficient method of capturing chinook during that period. From mid-to-late June set nets in the lower section of the Upper Stratum (primarily at Sandy River) were used to catch and tag fish until the fishwheels started to catch chinook starting the week of 20-26 June. From this period onward, virtually all of the tagged fish were caught in the fishwheels which were near Gitwinksihlkw (the middle section of the Upper Stratum, Fig. 2).

The number of active radio tags during each week was less than the total number of chinook that had been tagged to that date because fish were caught, fish died due to predation or handling, tags were regurgitated, or tags stopped transmitting. Table 7 shows the number of tags that we estimated were transmitting at the end of each period and could have been picked up during our surveys. A high proportion ( $50 \%$ ) of the fish that were tagged in May and early June were removed from the list of active tags before they reached their destination; all but one of these were removed by 16 June.

## Tracking Summary

During this study we obtained almost one million individual records of chinook salmon locations. These data were condensed to 4,149 records of chinook salmon locations (excluding recapture information and a few records of fish recorded more than once and at different locations on the same day) that were unique to fish, date and tracking method (Table 8). About half ( $47 \%$ ) of the unique records were obtained from our fixed-station receivers and the other half ( $53 \%$ ) from mobile tracking. As the fish moved up the main river, different tracking methods became important for documenting the movements. During June and early July, most fish were tracked from the boat, and as the fish moved up the river most tracking was done by the fixed-station receivers. Finally, as fish arrived on the spawning areas, most fish were tracked by helicopter and ground surveys.

Fate of Tagged Fish: We were able to determine the spawning destinations of $81 \%$ (291) of the 360 fish that were tagged (this was $98 \%$ of the 296 fish with active tags that escaped in-river fisheries, Table 9). Five other fish were alive and active, but we could not determine a spawning destination for them; one fish was moving up the Nass River north of Meziadin River on 24 September, two fish were tagged late in the study (12 and 24 Aug) and had not moved into their spawning areas, one fish appeared to be a non-spawner and the status of the last fish could not be determined. Seventeen radio-tags were returned from mainstem fisheries, 16 from Nisga'a net fishermen and one from an angler.

The fate of the 47 remaining radio tagged fish is not known for certain, but 24 tags were tracked at the location for several weeks. We suspect that 18 of these fish regurgitated their tags (11 at tagging sites and seven as a result of being caught by in-river net fisheries), and six fish died (tags were stationary, but not adjacent to a known fishing site). Our assessment of the fate of the remaining 23 tags was based on the movement patterns that were recorded for those tags; 10 were suspected to have been removed by native (nine) and sport fisheries (one); 10 were never tracked and may have been defective tags; and three tags stopped transmitting at sites upstream of the known fisheries (Table 9). Of the 16 tags suspected to have been removed by native fisheries, 10 were last tracked at fishing sites above Nass Bridge.

Up-river Movements: When the water levels declined in early July the fish from all stocks moved up-river together (Fig. 5).

Up-river movements were rapid and no particular stock seemed to lead or lag the general movement (Fig. 6 and 7). Most of the fish moving up-river by each of our fixedstation receivers passed a particular station over a period of about 10 d . Some of the fish that are shown to the far right on each panel in Figures 6 and 7 are fish that returned down river to spawning locations after migrating further upstream. Fishwheel data indicate that the peak movements of chinook past Gitwinksihlkw were from 24 June to 13 July. During this period there was a 4 -d hiatus from 30 June to 3 July when rising water levels curtailed
chinook migration (Fig. 5). This high-water event resulted in two distinct peaks of migration (27 June and 6 July).

Peak movements past FS1 were on 11 and 15 July, but the hiatus observed on the lower river was less pronounced at FS1 (Fig. 6). Rates of movement between these stations were $1-1.5 \mathrm{~km} / \mathrm{d}$ (Table 10). By the time that the peak movement arrived at FS3 on 19 July the two distinct pulses of fish that were observed at Gitwinksihlkw had consolidated into one pulse. The average rate of movement increased to $5.7-6.5 \mathrm{~km} / \mathrm{d}$. After chinook passed FS3 their rates of movement increased to $8-18 \mathrm{~km} / \mathrm{d}$ (Table 10). Single peaks of movement were observed at FS8, FS9, FS5 and FS7.

Fish that were entering a tributary that was a spawning destination tended to remain at the junction of that tributary and the mainstem Nass for a longer time than those continuing up the mainstem (Table 10). In addition, fish that overshot their destination tributary spent more time at each of the upstream tributary junctions than they did at downstream junctions. This latter observation results from fish passing the upstream junctions twice; once as they moved upstream and once as they returned downstream to their destination tributary.

Destinations: We were able to determine spawning destinations for 291 of the chinook that we radio tagged. The most important spawning tributaries were the Bell-Irving system ( 72 tags, $25 \%$ ), Cranberry/Kiteen system ( 59 tags, $20 \%$ ), Damdochax system ( 56 tags, $19 \%$ ), Kwinageese ( 32 tags, $11 \%$ ) and Meziadin River ( 26 tags, $9 \%$; Table 9). Except for the large number of tags in the Bell-Irving system, these estimates are within the ranges of historical escapement proportions (Table 1).

Fish that were tagged on the lower river both early and late in the season were almost exclusively lower-river fish; whereas, those tagged during the main part of the run from midJune to mid-July included all of the stocks.

Aerial Survey Efficiency: Efficiencies of aerial surveys from Damdochax Creek and Cranberry River range from $47-96 \%$ based on the number or radio-tags recorded during complete surveys of the systems versus the number of radio-tags known to have entered the system (Table 11). These efficiency estimates do not consider fish that may have temporarily left the system or radio tags that stopped transmitting; thus, these estimates may underestimate the true efficiency. In addition, most of these surveys were conducted secondary to visual counts and survey conditions were not always optimal.

Spawning-area Residence Time: The radio tags also permitted us to document the arrival date of individual fish into tributaries such as Damdochax Creek. A fixed-station receiver at the confluence of the Nass River and Damdochax Creek permitted us to determine the date and time when a radio-tagged fish entered, and in a few cases, left Damdochax Creek. When a radio-tagged fish was recovered and its date of death was estimated we were able to estimate the residence time of that fish in the system (Table 12). The departure date of a few live fish was also determined from the fixed-station data, but these fish are not
included in Table 12. Female and male chinook salmon spent an average of 25.3 and 30.4 d, respectively, in Damdochax Creek before they died or left. These residence times were not significantly different ( $\mathrm{t}=1.66, \mathrm{P}=0.109$ ).

## Spaghetti-tagged Chinook

A total of 74 chinook salmon that were not needed for the radio-tagging component of the study were spaghetti-tagged at the fishwheels between 8 July and 13 August (Table A-5). Three, one, and two tags were recovered on Damdochax Creek, on Cranberry River, and at Meziadin River (one from the fishway and one from a sport fisherman), respectively. In addition, two spaghetti tags were counted, but not recovered, from chinook passing through the Meziadin fishway. Table A-5 summarizes the number of tags applied and the recoveries by area.

## FIELD SURVEYS AND ESCAPEMENT ESTIMATES

A total of 56 aerial visual, 155 aerial telemetry (including the visual surveys), 16 ground count and 20 carcass recovery surveys were conducted from 13 July to 24 September 1992. The chinook escapement field survey effort and the radio-tracking effort are summarized in Table 5 and Appendix D. The Meziadin fishway ( 16 July to 5 October) and the Kwinageese weir (17 July to 23 September) were staffed for 82 and 67 d, respectively (Appendix E).

The majority of fish visually counted were seen in three systems (Damdochax, Kwinageese and Cranberry). The peak counts of live fish from combined aerial and ground surveys for these three systems were $2,175,1,659$ and 1,490 , respectively (Table 13). The dates, survey conditions, aerial and ground counts, estimates of observer efficiency, and reach descriptions for the escapement field surveys are provided in Appendix D. Damdochax Creek was the most intensively and frequently surveyed area with seven aerial and five ground surveys conducted from 4 August to 16 September. The counts obtained during field surveys and the derivation of escapement estimates for each system that was surveyed are described below.

## Damdochax Creek

Field Surveys: Damdochax Creek was divided into five reaches to stratify the survey counts and to monitor the upstream migration (Fig. 3). Counts of holding, spawning and total live chinook salmon for each of these reaches are given in Table 14 for each of the eight survey dates. The total counts of live chinook salmon (escapement curve) for all of Damdochax Creek and the counts of dead chinook for reaches 4 and 5 are plotted in Figure 8. Table 15 summarizes the live counts from the tributaries of Damdochax Creek which include Slowmaldo, Yaza, Sansixmor, and Wiminasik creeks. Table D-2 contains dates, survey conditions, aerial and ground counts, estimates of observer efficiency and reach descriptions for all visual surveys conducted on Damdochax Creek in 1992.

The peak estimate of live chinook salmon in Damdochax Creek was 2,175 on 21 August; this estimate was obtained from the ground survey count for reaches 4 and 5 and the aerial survey count for the remainder of the stream (Table 14). The peak aerial count of live chinook salmon in Damdochax Creek occurred on 27 August, when 2,090 fish were seen from the air (Table D-2), but the total live count was revised downward to 2,041 based on ground counts of reaches 4 and 5 . The peak total count of chinook $(2,199)$ was on this date when 158 dead chinook where counted. Peak counts of 1,495 holding fish, 923 spawning fish, and 617 dead fish (only reaches $4 \& 5$ were systematically surveyed for dead fish) were recorded on 10 August and 3 and 10 September, respectively (Tables 14 and D-3).

The spawning activity in Damdochax Creek exhibited two distinct, spatially and temporally separated peaks. For reaches 1-3, peak spawning activity occurred on 21 August when a total of 375 spawning fish were observed. For reaches 4 and 5, the peak occurred on 3 September when 809 spawning fish were observed (Fig. 8).

The spawning activity in Slowmaldo and Yaza creeks (tributaries of Damdochax Creek) appeared to occur earlier than the spawning activity in reaches 1-3 of Damdochax Creek. There were approximately 10 abandoned redds seen during the 17 August survey and the 16 live fish that were observed appeared to be in an advanced stage of spawning (i.e., fish had worn and discoloured tails and patches of fungus on the body).

The spawning activity in Wiminasik Creek appeared to be later than that observed in Slowmaldo and Yaza creeks. The peak count in Wiminasik Creek was on 26 August when 33 spawning fish were observed during a ground survey (M. Galesloot, Triton Environmental Consulting Ltd., Richmond, BC, pers. comm.)

It is uncertain whether or not chinook salmon spawned in Sansixmor Creek during 1992. It was surveyed once on 17 August; only one holding chinook was seen. The fish was 0.5 km upstream from the confluence of Sansixmor and Damdochax creeks.

A total of 56 radio-tagged chinook salmon were tracked to Damdochax Creek. Three of these were subsequently tracked to Slowmaldo Creek and one to Wiminasik Creek. A total of 1,382 adult chinook carcasses were examined for radio and spaghetti tags; most of these were in reaches 4 and 5 of Damdochax Creek, but a few fish (21) were examined in reach 3 on 3 September. A total of 23 radio tags and three spaghetti tags were recovered from carcasses. The peak carcass count was on the 10 September ground survey when 617 fish were examined for tags (Table D-3).

The observer efficiency during four aerial surveys of reaches 4 and 5 averaged $100 \%$ and ranged from 75 to $117 \%$ (Table 16). This assumed that the ground survey counts on the same date were the true counts.

The residence time estimated from the peak live count ( 21 August) and the peak dead count ( 10 September) was 20 d (Fig. 7). This was $29 \%$ less than the radio-tag-derived estimate of 28 d (Table 12).

Escapement Estimate: We calculated the escapement to Damdochax Creek to be 3,268 and 2,348 using the AUC technique and a stream residence time of 20 and 28 d , respectively. For the same area and using the carcass recovery data, we calculated an adjusted Petersen estimate of 3,054 , with $95 \%$ confidence limits of 2,071 and 4,699 (Table 17). These bounds include the AUC estimates based on both estimates of residence time. For the entire Damdochax system we calculated an adjusted Petersen estimate of 3,283 with $95 \%$ confidence limits of 2,227 and 5,053 .

## Cranberry/Kiteen Rivers

Field Surveys: The turbid water in the Cranberry River made surveying from the air difficult in 1992. The visibility into the water was good when the first visual survey was conducted. By 19 August, the water had become cloudy and fish could not be seen in water deeper than 1.5 m . After the 19 August survey, the visibility into the water deteriorated further and only fish in shallow water $(0.2 \mathrm{~m})$ could be seen during the final survey on 2 September.

The peak visual count of chinook salmon on the Cranberry River was obtained on 19 August when 1,490 fish were recorded (Table 18). It is difficult to determine the precise timing of peak abundance because the poor visibility into the water disproportionately affects the counting of holding and spawning fish. Holding fish are in deeper water and, therefore, are more difficult to see than spawning fish.

Despite the biases noted above, the field survey data suggest that there were at least two temporal components to the spawning activity in the Cranberry River in 1992. When upper Cranberry River (upstream of the last logging bridge and upstream of Weber Creek) was surveyed on 13 August, numerous ( $>20$ ) abandoned redds were observed and 128 of the remaining 133 live fish that were counted in this reach were classified as spawning. In addition, these fish were predominately lone males indicating that spawning activity was near completion. By 19 August, there were only 88 live fish observed in the same area, in comparison to 133 recorded the previous survey. Spawning activity in this upper reach contrasts sharply with that in the lower reaches of the Cranberry (downstream of the last logging bridge) where nearly 2.5 times more fish ( 1,490 vs 590 ) were seen on the 19 August survey than on the 13 August survey. This higher count on 19 August was made despite poorer visibility into the water because the turbidity had increased between the two surveys (Table D-2).

The aerial counts for the Kiteen River were 64 and 55 chinook for the 13 and 19 August surveys, respectively (Table D-2). The visibility into the water was limited on both surveys ( $<1.5 \mathrm{~m}$ ) and made complete enumeration difficult. All fish observed during both
surveys were classified as spawning, suggesting that spawning activity peaked on or before mid-August; this agrees with L. Jantz (DFO, Prince Rupert, B.C., unpubl. data) that the peak of spawning activity on the Kiteen River occurs during mid-August.

A total of 59 radio-tagged chinook entered Cranberry River (Table 9) based on data from the fixed-station receiver at the mouth of Cranberry River (FS3, Fig. 1) in combination with data from aerial telemetry surveys. Of these 59 fish, nine were subsequently tracked in the Kiteen River.

Escapement Estimate: Our minimum escapement estimates for the Cranberry and Kiteen rivers are 1,493 ( 1,490 live chinook counted on 19 August, plus three dead fish counted on 13 August and 64 on 13 August), respectively (Table 20). Both estimates are based on the counts after the completion of the sport fishery that occurred in July.

All radio-tagged fish that entered the Cranberry/Kiteen system were used to calculate the mark-recapture estimate. Thus, the estimate includes fish that were caught in the sport and native fisheries within the system. We calculated a single mark-recapture estimate for the entire system because some fish that were caught by sport fisherman were removed before they had a chance to enter Kiteen River. The net escapement to the Cranberry/Kiteen system was calculated by subtracting the sport fishery harvest of 556 chinook (Bocking and English 1993) and suspected native harvest of 122 fish (based on radio-tag tracking) and native fisheries within the system from the mark-recapture estimate of 3,603 (Table 20). Therefore, the net escapement estimate to the Cranberry/Kiteen system was 2,925 .

We calculated separate mark-recapture estimates for the number of fish that entered Cranberry and Kiteen rivers, but we were unable to determine what proportion of each stock was represented among the radio tags that initially entered the system because of the removal of some Kiteen River fish before they reached the Kiteen River. The net escapement to Kiteen may be reflected in the prorated mark-recapture estimate (550) because most fish that were tracked in the Kiteen had already made it past the sport fishery. However, the extent of the sport fishery biases among our data are not known. Assuming that the mark-recapture estimate represents escapement to the Kiteen River, then escapement to Cranberry was 2,375 ( 3,603 less 550 less 678 ). This estimate may be low because some of the sport fishery catch was from the Kiteen.

To independently verify the validity of the mark-recapture estimate derived for the Cranberry River, we calculated the observer efficiency that would have been required during the aerial surveys to generate an AUC estimate similar to the mark-recapture estimate. Table 19 shows a series of AUC escapement estimates based on a range of mean residence times. Assuming a mean residence time of 28 d , an observer efficiency of approximately $45-50 \%$ was necessary across the four surveys to derive an AUC escapement estimate of 2,400 (Table 19). Given the turbid water conditions in the Cranberry River during most of the summer in 1992, it would be reasonable to expect this level of observer efficiency.

## Kwinageese River

Field Surveys: The Kwinageese weir was operated from 17 July to 24 September in 1992. The adjusted electronic and visual counts of fish passing through the weir are presented in Tables E-2 and E-3. These data have been provided by Triton Environmental Consultants. Figure 9 shows the estimated daily counts of chinook salmon passing through the weir based on bypass and index counts and estimates extrapolated from index and electronic counts.

A total of six aerial count surveys, 11 aerial telemetry surveys, and four ground surveys were conducted on the Kwinageese River in 1992 (Table D-2). The peak count was made on 2 September when 1,659 live (1,354 above and 289 below the weir; 16 in Shanalope Creek) and 20 dead chinook were recorded (Table D-2). A total of 32 radiotagged fish were tracked in the Kwinageese River; 23 moved above the Kwinageese weir, and nine remained below the weir.

Shanalope Creek, a tributary of the Kwinageese River, was surveyed three times (Fig. 1, Table D-2). Chinook salmon (primarily spawning fish) were observed in the first kilometre upstream of the mouth of the creek; seven, 21 and 16 fish were observed on 18 August, 26 August, and 2 September, respectively.

Escapement Estimate: The minimum estimate of the chinook escapement to the Kwinageese system (including Shanalope Creek) of 1,684 and is based on counts made during the 2 September (Kwinageese River) and 26 August (Shanalope Creek) aerial surveys. The minimum escapement estimate for above the weir is 1,354 based on the live count from the 2 September survey. The minimum escapement estimate for the area below the weir is 330 based on counts of live and dead fish during the same aerial survey below the weir and the 26 August survey of Shanalope Creek.

Triton Environmental Consultants, Richmond, BC (unpubl. data) derived an estimate of the chinook escapement above the weir on Kwinageese River using data obtained at the weir. The estimate is 1,799 adult fish and is composed of 686 chinook salmon observed passing through the bypass panel (includes fish sampled for length and scales and released alive above the fence) and 1,113 chinook estimated to have gone through the electronic counter when it was not staffed (Table E-2) and is based on actual counts of only 88 chinook during index counts (Table E-3).

We also calculated an adjusted Petersen estimate using our carcass recovery data from Kwinageese River and the total number of radio tags known to be in the system. This estimate is 2,132 adult chinook salmon; 600 and 1,532 of these were estimated to be below and above the weir, respectively. The $95 \%$ confidence limits of the overall estimate were 1,260 and 3,850 .

We used the mark-recapture estimate based on the radio-tag data as the best estimate of chinook escapement to the Kwinageese River (2,132, Table 21) because of potential biases in the estimates from the weir (see Discussion).

## Meziadin River

Field Surveys: The fishway was staffed and operated from 16 July to 5 October ( 82 d), including the start and end date. During this time, 870 adult and 85 jack chinook salmon were enumerated (Table E-1). Daily counts of adult and jack chinook at the fishway are presented in Figure 1. Although chinook were recorded moving through the fishway from 19 July to 2 October, $43 \%$ of the 870 adult chinook moved through the fishway during a 4-d period from 27-30 July and $63 \%$ were counted during a 11-d period from 26 July to 5 August.

A total of 13 telemetry and three visual surveys by helicopter were made of the Meziadin River (Table 5). A peak count was made on 6 September when 292 chinook were counted above and 40 chinook were counted below the fishway. Of the 292 fish observed above the fishway, 142 were holding and 150 were spawning (Table D-2). In addition, 30 chinook carcasses were counted above the fishway. All 40 fish observed below the fishway were spawning.

Surprise, Strohn and Hanna creeks (tributaries of Meziadin Lake) were surveyed by helicopter (visual and telemetry surveys were conducted concurrently) once in 1992. Surprise and Strohn creeks were surveyed on 14 August and Hanna Creek was surveyed on 18 August. Except for poor visibility into Surprise Creek, survey conditions were good and no chinook salmon were observed and no radio-tagged fish were detected.

Escapement Estimate: We derived a minimum estimate of the chinook escapement to Meziadin River of 910 , based on the 870 fish through the fishway and the 40 fish observed spawning below the fishway during the 6 September aerial survey (Table 21).

We derived a prorated adjusted Petersen escapement estimate of 1,588 chinook based on the radio-tag data; $73 \%$ of these fish were estimated to have spawned above the fishway. This is our best estimate of the total escapement to the Meziadin River in 1992 (Table 21).

## Bell-Irving River

Field Surveys: A total of 72 radio-tagged chinook were tracked moving toward a destination in the Bell-Irving system either by the fixed-station receiver located at the junction of the Bell-Irving and Nass Rivers or by surveys conducted in the system. The distribution of these tagged fish within the watershed was determined by four aerial and four ground surveys (Table D-2). All but seven radio-tagged fish that entered the Bell-Irving River were subsequently tracked to a specific spawning area.

The spawning destinations of radio-tagged fish in the Bell-Irving watershed are summarized in Table 20. The majority of the fish that were visually counted in the BellIrving watershed were observed in Teigen and Oweegee creeks where peak visual counts were 476 ( 475 live, 1 dead) and 450 fish, respectively. In addition, 40 and 12 radio-tagged fish were recorded in Teigen and Oweegee creeks. The remainder of the fish that were visually counted in the Bell-Irving watershed were observed in the mainstem of the BellIrving River (peak count of 58 fish), Snowbank Creek (29), Taft Creek (18), and Hodder Creek (5). In addition to Teigen and Oweegee creeks, radio-tagged fish were found in the mainstem of the Bell-Irving River (14) and Taft Creek (6). All systems that were surveyed except Teigen and Oweegee creeks were turbid and the fish that were counted probably represent a fraction of those that were present.

All of the fish that were observed in Snowbank and Teigen creeks on 18 August (first survey) were spawning and it appeared that the peak of spawning activity had occurred previous to the survey. By the 5 September survey, the die-off was nearly complete and only 45 fish were seen. The timing of the spawning activity in 1992 was earlier than historical data (L. Jantz, DFO, Prince Rupert, B.C., unpubl. data). These data suggest the following timing of activities for chinook in Teigen Creek: arrival in early August (midAugust for Teigen); start of spawning in late August; peak spawning in early September; and die-off in late September.

Spawning activity of chinook was later in Oweegee Creek than in Teigen and Snowbank creeks. During all surveys, including the last survey on 6 September, the majority of fish were holding (Table D-2). On the 20 August survey, only three of the 450 fish that were observed were spawning. The timing of spawning activity in Oweegee Creek in 1992 was similar to historical data (L. Jantz, DFO, Prince Rupert, B.C., unpubl. data). However, low water levels and log jams on Oweegee Creek during August, may have delayed the spawning activity in Oweegee Creek in 1992. Mature fish were observed holding in deep holes in the lower 200 metres of the stream and extremely heavy bear activity was seen throughout the creek. Most live fish found upstream of the delta of Oweegee Creek showed signs of bear predation (scrapes) and the few carcasses that were encountered were pre-spawn mortalities due to bear predation.

Survey conditions were poor for aerial surveys of Taft, Rochester, and Hodder creeks and we were unable to assess the stage of spawning activity. The visibility into Taft and Rochester creeks was severely limited ( $<0.2 \mathrm{~m}$ ) and the tree canopy covered much of Hodder Creek.

Escapement Estimate: We determined the minimum escapement to the Bell-Irving watershed to be 1,036 based on the peak live counts from the field surveys conducted on 18 and 20 August (Table 20). The prorated adjusted Petersen estimate of escapement to the entire Bell-Irving watershed was 4,397 adult chinook based on the 72 radio-tagged fish tracked to the watershed and the overall Nass adjusted tag rate. Based on the different tag
recovery rates recorded in different tributaries, the range of escapement estimates is 4,161 to 4,667 adult chinook salmon (Table 20).

The minimum escapement estimates for Teigen/Snowbank, Oweegee, Bell-Irving, Taft, and Hodder (based on visual surveys) were 505, 450, 18 and 5, respectively. Our best estimates for Teigen/Snowbank, Oweegee, and Taft based on the prorated mark-recapture data were 2,$443 ; 733$; and 366 , respectively (Table 20).

The 14 radio-tagged chinook that were assigned to the mainstem included all fish that were detected in the Bell-Irving River, but not in any of its tributaries. Although we know that these fish spawned in the Bell-Irving watershed, we are unable to conclusively identify a final spawning location for many of these fish from the data collected during this study. Some spawning fish were observed on the Bell-Irving mainstem (33 of 58 counted on 20 August, but due to the limited survey effort, we could not determine if some of the radiotagged fish present in the mainstem were headed to a tributary or if they had spawned in a tributary and subsequently dropped back into the mainstem. Given that much of the spawning activity appeared to have been completed in Teigen and Snowbank creeks, the latter scenario is quite possible. The 14 tagged fish represent an estimated 855 fish that may have spawned in the mainstem, any of the tributaries mentioned above or in streams not surveyed.

## Upper Nass Mainstem

The Upper Nass Mainstem includes the mainstem Nass River from the Cranberry River mouth upstream to the headwaters and all minor tributaries along this section of the Nass River where fish were observed within $1-2 \mathrm{~km}$ of the river.

With the exception of the systems listed below, none of these areas were surveyed to obtain visual counts of chinook salmon. However, virtually all of the mainstem and adjacent tributaries as far north as Panorama Creek were surveyed for radio tags while we were transiting between survey areas, fixed stations, or fuel caches; thus most if not all, radiotagged fish were present in this area were detected.

Six radio-tagged fish representing 366 chinook had spawning destinations in the Upper Nass Mainstem area. If the different tag rates observed in the different tributaries are used, rather than the overall rate, the estimates range between 347 and 389 fish (Table 20). Based on our visual and telemetry surveys, these fish were dispersed throughout the system in small groups.

## Upper Nass Tributaries

Muskaboo Creek: A single aerial survey of Muskaboo Creek was conducted on 17 August. The survey conditions were moderate (visibility into the water approx. 0.5 m ) and six fish were observed spawning in the lower 100 m of the stream. All of these fish were
very large ( $>16 \mathrm{~kg}$ ) and appeared to be nearing completion of spawning. No radio-tagged fish were tracked in Muskaboo Creek, but the helicopter speed was too fast for efficient recording of radio tags. In addition, this area was north of our normal travel corridor so that radio tags could not be recorded during incidental surveys.

We estimated the minimum escapement to Muskaboo Creek as six fish. This count is likely an underestimate due to the relatively poor water visibility. There is no evidence, other than the observation of six spawning fish, about the timing of spawning activity in Muskaboo Creek.

Kotsinta Creek: A single aerial survey to conduct visual counts of Kotsinta Creek was conducted on 3 September. In addition, the lower portion of the creek was tracked opportunistically several times while the tracking aircraft was flying to and from Damdochax Creek (Fig. 1). Survey conditions were good on 3 September and 10 live and one dead fish were observed in the lower 0.5 km of the stream (Table D-2). In addition, eight abandoned redds were observed and the remaining live fish were predominately lone males. The spawning activity appeared to be near completion.

No radio-tagged fish were tracked during the 3 September survey, but one was tracked in Kotsinta Creek on 21 and 27 August while the survey crew was transiting to and from Damdochax Creek.

We estimated the minimum escapement to Kotsinta Creek as 12 fish based on the 10 live, one dead and one radio-tagged chinook recorded on the 27 August and 3 September surveys (Table 20). This count is an underestimate of the true escapement because the survey occurred after the peak of spawning activity, the remaining live fish were lone males and the eight abandoned redds that were recorded indicate that females had been present.

Saladamis Creek: An aerial survey of Saladamis Creek was conducted on 27 August. The survey conditions were good and no live fish, carcasses or signs of fish (redds) were observed (Table D-2). In addition, no radio-tagged fish were detected.

## Lower Nass Mainstem

The Lower Nass mainstem includes the mainstem Nass River from Lakalzap to the mouth of the Cranberry River and all minor tributaries in this portion of the river where fish may have spawned within $1-2 \mathrm{~km}$ of this section of the main river. This area was surveyed opportunistically during surveys throughout the 1992 field season. No fish were observed in the mainstem of the Nass River. The river was very turbid and visibility into the water was usually less than 20 cm . Six radio-tagged fish that were tracked only in the mainstem and are believed to have spawned in the lower Nass River. If we assume that the mark rate for this group was similar to that derived from surveys of upper river stocks, these six tags represent an escapement estimate of 366 fish (Table 20). This estimate is likely to be an underestimate of the numbers of chinook in the area because many of the fish destined for
this portion of the river would not have been available for capture at our primary tagging site at Gitwinksihlkw. Therefore, the actual mark rate (tagged fish/untagged fish) for these chinook was probably much lower than that estimated from carcass surveys of upper Nass stocks.

## Lower Nass Tributaries

The Lower Nass tributary category includes all major or moderately important spawning streams in the lower Nass River between Lakalzap and the Cranberry River. Each of these streams in discussed below.

The total number of chinook in the lower Nass tributaries was estimated by prorating the overall mark-recapture estimate ( 18,117 in Table 20) by the portion of the radio tagged fish tracked to all lower Nass tributaries. This estimate was 2,077 adult chinook with a range of 1,965 to 2,204 based on different tag rates from different up-river tributaries. These estimates probably underestimate the number of fish entering lower Nass tributaries for the same reasons provided for the lower Nass mainstem spawners.

The above estimates represents escapement prior to removals by sport fishermen. Bocking and English (1993) estimated that 630 chinook were caught by sport fisherman on Tseax River and Slough. Thus, the net escapement to the lower river systems would be 1,444 adult chinook.

Tchitin River: The Tchitin River was surveyed by helicopter twice to count chinook in and near the river (i.e., holding at the mouth of the river). In addition, fish were tracked on several occasions while the survey crew was transiting to other locations. Conditions for visually surveying the stream were poor during both aerial surveys; only three and seven fish were observed during the 4 and 18 August surveys, respectively (Table D-2). The six radiotagged fish that were tracked to the Tchitin River represent a prefishery escapement of 366 adult chinook.

Seaskinnish Creek: Three systematic and three opportunistic aerial telemetry surveys were conducted of Seaskinnish Creek. A total of 145 live chinook was counted during an aerial count on 19 August and 91 live fish and 16 carcasses were counted during a partial ground survey on 28 August. Radio tracking was conducted on both of these surveys (Table D-2). Conditions for visually counting fish were poor on the aerial survey due to the overhanging tree canopy along much of the stream. The minimum escapement estimate to the Seaskinnish Creek was 145 adult chinook based on the peak count on 19 August. The best total escapement estimate is 916 based on the 15 radio-tagged fish tracked to Seaskinnish Creek.

Tseax River: Five telemetry surveys were conducted of Tseax River and Slough. A visual count was attempted on the 19 August survey, but turbid water made counting from the air impossible and no chinook were observed. Nine radio-tagged chinook were tracked
into this system which produces an escapement estimate of 551 chinook for the Tseax River and Slough before the sport fishery harvest. However, the estimate was lower than the estimated sport harvest of 630 from this system (Bocking and English 1993), and is clearly an underestimate for this system. The peak of spawning in this system (early October) was 2-3 wk after termination of this study and three of the radio-tagged fish ( 2 south of Tseax River and one tagged 29 August that was not tracked) may have entered Tseax after termination of our surveys. In addition, many of the fish that spawn in Tseax arrive in the Nass River late in the summer and may not be represented among our radio-tagged fish. Historical data (L. Jantz, DFO, Prince Rupert, B.C., unpubl. data) identifies the Tseax system as having the latest spawning run of Nass River chinook stocks. Therefore, the Tseax stock is the most susceptible stock to biases associated with our reduced tagging rates late in the season.

Miscellaneous Nass Tributaries: No fish were seen during combined visual/telemetry surveys of Kwinatahl, Shumal, Zolzap, Ksedin and Anudol creeks, but visibility into the water was severely restricted in all creeks except Zolzap which was clear. In addition, telemetry surveys were conducted of the mouth of these creeks each week throughout the summer by boat. No fish were observed in any of these creeks during the study, but three radio-tagged fish were detected in Anudol Creek and at least two of them appeared to spawn there (Table D-2).

## Other Systems

Ishkeenickh River: One aerial survey was conducted of the Ishkeenickh River on 14 August. Survey conditions were reasonably good and the surveyor estimated that his counting efficiency was $50-80 \%$ (Table D-2). A total of eight holding and 67 spawning fish were observed and no radio-tagged fish were recorded in the system. Approximately 12 abandoned redds were observed and most of the spawning fish were in an advanced stage of spawning. Typically, the spawning activity of Ishkeenickh River chinook peaks in late August (L. Jantz, DFO, Prince Rupert, B.C., unpubl. data).

Based on the predominance of spawning fish observed during the 14 August survey, there are three scenarios that could describe the spawning activity in 1992: 1) the survey was done during the peak of spawning activity and the total escapement was very low; 2) the peak of spawning activity had already occurred and higher numbers of fish were present earlier; or 3) an early component of the run was at or past the peak of its spawning activity and a second run of fish would arrive later that was not present during the survey. From the single aerial survey results we are unable to determine which of these scenarios is correct.

We estimated the minimum escapement to the Ishkeenickh River as 75 adult chinook and our best estimate as 115 fish (adjusted for $65 \%$ average observer efficiency), recognizing that it is still an underestimate because it represents only a single live count. This estimate does not include an estimate of the number of fish that entered the stream, spawned and died
prior to the survey date (i.e., those that spawned in the abandoned redds) or an estimate of the number of fish that entered the stream after the survey date.

Kincolith River: One aerial survey of the Kincolith River was conducted on 14 August. Survey conditions were reasonably good and the surveyor estimated the observer efficiency at $80 \%$ (Table D-2). A total of 32 spawning fish were observed and no radiotagged fish were recorded in the system. Numerous ( $>50$ ) abandoned redds were observed and the 32 spawning fish were in an advanced stage of spawning. Typically, the spawning activity of chinook run to the Kincolith River peaks in mid-August (L. Jantz, DFO, Prince Rupert, B.C., unpubl. data). Based on the predominance of spawning fish and the numerous abandoned redds, it appears that in 1992 the peak spawning activity had already occurred by mid-August.

We estimated the minimum escapement to the Kincolith River as 32 adult chinook and our best estimate as 40 (adjusted for $80 \%$ observer efficiency), recognizing that this is definitely an underestimate because it represents only a single live count conducted after the peak spawning activity. This estimate does not include an estimate of the number of fish that entered the stream, spawned and died prior to the survey date and the observation of greater than 50 abandoned redds suggests that larger numbers of fish were present earlier.

## Total Nass River

Our best estimate of the numbers of chinook arriving at spawning destinations in the entire Nass River system is 16,809 (i.e., total escapement to tributaries less tributary specific harvests) (Table 21) with $95 \%$ confidence limits of $11,000-27,000$. Escapement estimates for Damdochax and Kwinageese were derived from tributary specific mark rates (Table 20). Escapement to other spawning areas were prorated based on the system wide mark rate (Table 20).

## DISCUSSION

Initially, the major goal of this program was to confirm the locations of major spawning areas for Nass River chinook stocks and collect information on in-river run timing. As the program developed, it became apparent that the combination of fisheries projects conducted in 1992 (fishwheels, fishway counts, weir counts and aerial surveys) could provide the data required to compute escapement estimates for all major chinook salmon stocks within the Nass watershed. In most areas, our best estimate is based entirely or partially on radio-tag tracking and a Petersen mark-recapture design. The mark-recapture design is not subject to many of the biases that were present in the methodologies. The biases present in the escapement methods used during this study are discussed below.

## AUC ESTIMATES

An evaluation of the potential biases in each of the estimates made using different methodologies permits us to determine which estimate is most likely to represent the actual escapement. Two estimates are used to calculate AUC. The first is the number of fish present in the system and the second is the mean residence time of each fish. During this study we attempted to count the number of fish during each survey and used the method that we believed would give the most accurate count. However, we did not expand our counts to take into account fish that were not recorded by the observer because they were under stream banks or trees, in deep holes where fish were difficult to see, or because the observer did not see or count them. Numerous studies have been conducted concerning the biases involved in aerial and ground surveys and the consensus is that counts always underestimate the number of individuals present. Even for constantly visible large terrestrial species only $30-90 \%$ of animals present were counted by single observers during aerial surveys (Caugley 1974). The degree of underestimation varies according to a large number of environmental factors and the experience of the observer (Eberhardt et al. 1979). The observer that conducted the surveys (Michael Link) was very experienced so that the biases were likely minimized. However, all counts were underestimates of the total number of fish present. Link estimated his efficiency to have been $80 \%$ or less during the aerial surveys conducted 10-27 August when peak numbers of chinook salmon were counted in Damdochax Creek.

The estimates of residence time from the peak-live to peak-dead counts (based on visual counts) are subject to large errors because surveys are conducted about 4-7 d apart and considering the above-mentioned biases in individual count the actual peak live abundance may not be the apparent peak live count. For example, the observer efficiency during the 17 August aerial survey was estimated to be $50-80 \%$, whereas the observer efficiency on 21 August (peak count) was $80 \%$. Thus the peak abundance may have been on or near 17 August and the residence time based on peak-live to peak-dead counts could be 24 d .

The residence time determined from the combined telemetry and carcass recovery data should be less biased than those obtained from the count data. Since the exact time of arrival in the survey area is known and the date of death is estimated to within 1-3 d.

## KWINAGEESE RIVER

One would normally expect counts obtained from a weir to provide an accurate estimate of escapement. However, in this case there were several factors that reduce the reliability of the estimates from the weir data. The index counts used to verify electronic counts and species composition only represented $8 \%$ of the fish passing through the counter. We were not given the statistical bounds around the species composition data, but suspect that they are large because fish movements were not steady but pulsive in nature. Another potential source of bias was the identification of jack chinook. M. Galesloot (Triton Environmental Consulting Ltd., Richmond, BC, pers. comm.) indicated that the counts of chinook included only adult fish because they were not able to distinguish jack chinook from
other small salmonids. Some of the technicians working on the weir also worked on other studies with us and had no problems distinguishing jack chinook from other species. Thus it is possible that some jacks are included among the chinook counts and that the number of adult chinook is overestimated because their calculations include some jacks. This bias would be low because jacks made up only $9 \%$ of chinook that passed through the Meziadin fishway (Table E-1) and at most some fraction of the $9 \%$ of all chinook that were jacks might have been included in the total count of chinook.

## MEZIADIN FISHWAY ESTIMATES

We used the actual counts of fish through the fishway as the minimum escapement estimate. These counts underestimate the true escapement because: 1) some fish bypassed the fishway by jumping over the falls; 2) some fish may have moved through the fishway before it was staffed; and 3) some fish may have moved through the fishway when it was left open after break-ins.

There is a falls adjacent to the entrance of the fishway that is believed to be impassable to most fish. This falls is approximately 65 m wide and varies between 1.5 and 5.0 m in height. During the salmon migration, numerous fish are seen jumping at the base of the falls and occasionally salmon are observed jumping over the falls (Stephan Jacob, LGL Limited, Sidney, BC, pers. comm.). The proportion of chinook that jumps over the falls has never been estimated, but it is believed to be small.

The fishway was left open and was not staffed from the autumn of 1991 until 16 July 1992. In 1992, chinook were first documented on the lower river in late April. There is a possibility that some chinook may have passed through the fishway before it was staffed. However, the first chinook salmon counted through the Meziadin fishway was on 19 July and only 18 chinook had been counted before 23 July. In addition, radio-tagged chinook were not detected at FS8 (just below Meziadin River) until 18 July although the station had been operating since 7 June (see Fig. 6 later). Based on this information, we believe that very few, if any, chinook passed through the fishway before it was staffed.

There were two instances between late July and early October, when vandals broke into the fishway during the day, probably took fish (primarily sockeye) from the holding pens below the counting chutes and left the gates open until the staff returned 1 to 2 h later ( D . Southgate, DFO Prince Rupert, pers. comm.). We examined counts before and after the break-ins and determined that few chinook were likely to have passed through the fishway during these periods so we did not adjust the escapement estimate.

## MARK-RECAPTURE ESTIMATES

Biases in Petersen estimates can occur when the principal assumptions of the estimation procedure are violated (p. 81-82, Ricker 1975). The relevant assumptions and how our study attempted to meet and/or test their validity are outlined below.

## 1. The marked fish suffer the same natural and fishing mortality as the unmarked fish.

The tagging and natural mortality rates can be estimated from the data. All but 10 of 360 radio-tagged chinook salmon were tracked and/or accounted for subsequent to release. There was a manufacturing flaw in a circuit in some of our tags that caused some tags to stop transmitting shortly after application. Based on the observed failure rate of tags that had not been applied, we believe that all or most of these 10 tags stopped transmitting. The major source of mortality among the radio-tagged fish was capture during the in-river net and sport fisheries. From the extensive tracking surveys, it was possible to monitor the behaviour of the tagged fish and to determine their mortality rate. We were also able to determine or guess at the causes of mortality of many of the radio-tagged fish for which the exact cause of death was unknown. For example, a few fish disappeared during late July in the vicinity of Nass Bridge (where the road to Alice Arm crosses the Nass River). Although no tags were returned by fisherman in this area, we suspect that most of these fish were caught by sport and native fishermen.

We assumed that any early mortality of radio-tagged fish was the result of tagging. Once fish had survived for more than a week we assumed any further mortality was due to natural causes or fishing. Studies of the effects of implanting ultrasonic tags in juveniles fish indicate that they recovered quickly ( $<4 \mathrm{~h}$ ) and permanently (permanently was $1-4 \mathrm{wk}$ in their study) if the tags were less than $5 \%$ of the body weight of the fish (Moser et al. 1990). During our study, tags were much less than $5 \%$ of the weight of the fish and only one radiotagged fish ( $0.3 \%$ ) died within a few days of being tagged. It was assumed to have died as a result of capture and handling.

The effects of any early tag mortality on the escapement estimates were eliminated by the data analysis methods that were used; only tagged fish that entered a specific stream were used in the estimation procedure. By the time that fish had entered their respective spawning streams, they had travelled for 2 to 10 wk and over distances of 20 to 300 km . Once the tagged fish had survived this upstream migration, we assumed that their mortality rate would be similar to unmarked fish. This seems reasonable given that only $1 \%$ ( 5 of 360 ) of the tagged fish died of unknown causes before they arrived at their spawning destinations and they died 3-8 wk after release.

## 2. Marked fish and unmarked fish are equally vulnerable to the recapture technique.

In this study, all of the recoveries came from carcass examinations. During ground surveys all dead fish were examined for tags. Since the operculum tag and transmitter antenna were not obvious unless the fish was examined quite closely, this recapture technique was non-selective. Other enumeration efforts at Meziadin fishway provided good estimates of chinook passage, but few observations of radio-tagged fish. Because our radio-tagged fish
did not have conspicuous marks, it is likely that some radio-tagged fish passed the observers without being detected. Therefore, mark rate data from the Meziadin fishway counts have not been used in determining mark rates.

## 3. The marked fish do not lose their marks.

This assumption can be tested using our data and any biases can be reduced or eliminated. Radio-tagged chinook were marked with two tags, a radio transmitter and an operculum tag. We examined each carcass carefully for both tags. Surveyors opened the mouth of each carcass, peered down the throat and looked behind each operculum for the radio-transmitter antenna. The outside of the operculum was scraped clean with the sharp end of a fish pew and examined closely for a tag scar (which was readily apparent, if present). Thus our marked fish would have been identified even if they lost both tags.

The only form of tag loss that would affect our escapement estimates were tags that stopped transmitting. We suspect that a maximum of 15 of the 360 radio tags applied may have stopped transmitting shortly after release. One of these fish was recovered in the Damdochax system. If these tags had functioned properly and been tracked to a spawning stream they would have increase our total escapement estimate. Since $81 \%$ of the other radio-tagged chinook were tracked to spawning areas it is possible that 12 of these fish were not detected during spawning ground surveys. This would result in the total escapement number being underestimated by 732 fish ( $4.3 \%$ ).
4. The marks are applied randomly over the entire run; and/or marked fish become randomly mixed with the unmarked fish; and/or the recovery effort is proportional to the number of fish present in different reaches of the system.

The best evidence that the radio tags were applied over the entire run comes from surveys of Damdochax Creek. Visual counts and radio-tag tracking data obtained from 7 surveys support the assumption that tagging was proportional to the run at least for this tributary (Figure 10). Migration timing data from the fishwheels indicated that most of the chinook run migrated upstream between 13 June and 17 July when $89 \%$ of the radio tags were applied. Analysis of daily recovery data from the Meziadin fishway for sockeye tags released from the fishwheels indicated that the fishwheels were catching a consistent portion of the total sockeye run during this period (Link et al. 1996). This information coupled with the observation that all stocks appeared to migrate together in 1992 (Fig. 5) supports the assumption that marks were applied randomly over the entire run.

This assumption is further supported by the potential for marked fish to mix with the unmarked population. The radio tags were applied to fish between 10 and 270 km from the spawning grounds, a distance that required 2-3 wk of travel time, and spawning was 2-10 wk after the fish were tagged. We believe this was sufficient time and distance for fish to have become randomly mixed.

Finally, we examined our data to determine if tagging was representative of all stocks by comparing marked-to-unmarked ratios among different tributaries. The marked-tounmarked ratios for Damdochax and Kwinageese based on carcass examinations were $1: 58$ and $1: 65$, respectively. Thus it appears that marked-to-unmarked ratios at the two up-river locations were similar. We do not have sufficient data to compare marked-to-unmarked ratios of lower river stocks. However, lower river stocks may have been over-represented by tagging efforts in May and June and under-represented by tagging efforts in late July to September. Overall lower river stocks were probably under-represented, but made up a relatively small proportion of the overall run in 1992.

## 5. All marks are recognized and reported on recovery.

We did not re-examine carcasses for missed tags to test this assumption. However, the surveyors were very experienced at doing carcass recovery work and ample time was allocated to examining carcasses. Furthermore, because surveyors looked for two tags on each fish (radio and operculum tags), they were unlikely to overlook both tags.

## CAPTURE METHODS

The proportion of fish that were tracked to their spawning destination did not appear to depend on the method of capture when all factors are considered. Seventy-five of 100 ( $75 \%$ ) fish tagged from nets were tracked to their destination in comparison to 216 of 260 ( $83 \%$ ) fish tagged from the fishwheels. However, 11 net-caught radio-tagged chinook were removed by the in-river net fishery or because the tags stopped transmitting by 25 June when the fishwheels started to catch chinook. Thus, 75 of $89(84 \%)$ net-caught fish that were still active on 25 June were tracked to their spawning destination.

## RUN TIMING

Data collected from the Meziadin fishway over the past 25 years provides a clear indication that the 1992 run began very late. The late beginning at Meziadin was compensated for by very high abundances moving up-river during the peak of the run such that the portion of the run passing through the fishway after the end of July was consistent with the 25 year mean. The compressed run timing in 1992 was probably caused by extremely high water during mid-to-late June and early July.

## HARVEST RATES

Harvests of chinook salmon by the major in-river gillnet and sport fisheries were estimated during other studies. In-river and estuary gillnet fisheries harvested an estimated 7,100 chinook between Gingolx and Grease Harbour (English and Bocking 1993) and sport fisheries harvested 1342 chinook, primarily from the Cranberry and Tseax rivers (Bocking and English 1993). We estimated that the first nations fishery above Grease Harbour harvested 612 chinook, based on the disappearance of 10 radio tagged fish that were last
tracked near known fishing sites within this portion of the river. Therefore, we estimated the total return to the river in 1992 to be roughly 26,000 chinook (Table 21). Based on this run size estimate, the Nisga'a in-river gillnet fishery harvested $27 \%$ of the fish that entered the Nass River. The sport fishery harvested only $5 \%$ of the total run, but harvested a much higher proportion of the Cranberry-Kiteen and Lower Nass stocks. The sport fishery rates were estimated at $11 \%$ ( 556 catch from a pre-fishery escapement of 5158 chinook) in the Cranberry-Kiteen and at $22 \%$ (630/2890) on the Lower Nass stocks.

The in-river net fishery harvest rate was modest given that the fishery was unregulated in 1992. The harvest rates would probably have been larger had river conditions in June been more favourable for fishing. The sport fishery harvest rates are the first rigorous estimates for this system. In the Cranberry-Kiteen watershed, we have no reason to suspect biases in either the catch or escapement estimates. The sport catch estimates appear reasonable, given the high level of effort expended on the Cranberry River in 1992, and the migration timing for this stock suggests that it was probably marked at a rate proportional to the up-river stocks. The same cannot be said for the Lower Nass stocks. The Tseax River is generally believed to support a large and later run chinook population. Given the timing of the peak sport fishery harvests on the lower Tseax (late August) it is possible that this run returned to the river later than the other stocks and was marked at a much lower rate. Therefore, it is likely that we have underestimated the escapement to Tseax and thus overestimated the sport and first nations fishery harvest rates for Lower Nass stocks.

## ACKNOWLEDGEMENTS

The success of this study was a tribute to the hard work and diligence of a large number of people through the study initiation, planning, conduct and analysis stages. We thank the staff of Nisga'a Tribal Council and especially Harry Nyce for his support and encouragement throughout this program. R. C. Bocking, the IMP program manager, planned most of the peripheral studies that contributed data to this study and ably and efficiently coordinated all of the 1992 field programs.
P. Wainwright, R. Frith, C. Fleek, and T. Nelson assisted in data analysis or preparation of the report. R.C. Bocking and the members of the Pacific Stock Assessment Review Committee, particularly J. Eiler and B. Riddell, reviewed the report and made comments that improved it.

The radio tags and tracking equipment were provided by Lotek Engineering. Jim Lotimer and Ron Batton made the conduct of this study possible, despite our last-minute commitment to the radio-tagging component of the project. Cam Grant and Stewart Strathearn provided excellent technical support that maximized data collection from the radiotagged fish. Ted Bjornn, Ken Tolotti and Rudy Ringe of the Idaho Cooperative Fish and Wildlife Research Unit graciously provided us with knowledge of the radio-tag tracking systems capabilities and their methods of collecting and processing data. Ian Swan of

Northern Mountain Helicopters piloted the helicopter during most flights and was ably replaced by Blair Savage.

Everyone working on the IMP project in 1992 contributed to the success of this study and we thank them all. Special contributions were made to the radio-tagging and tracking component by Richard Alexander, Clyde (William) Azak, Jennifer Azak and Terry Morven and to the escapement surveys by Courtney Fleek, George Gosnell, Jr., Carl Johansen, Arthur Nyce, Stephen Nyce, Brenda Nass, Dean Ryan, Leonard Squires and Barry Stevens.

Funding for this project was provided by the Canadian Government as part of the Nisga'a - Canada Interim Measures Program.

a - The first chinook was tagged on 15 May and the last chinook was tagged on 29 August.
b- Upper section of the Upper Stratum is from Grease Harbour to the outflow of Tseax Slough; Middle section is from the outflow of Tseax Slough to the outflow.of Zolzap Slough; Lower section is below the outflow of Zolzap Slough (primarily at or near Sandy River).
c - These fish were in the Lower Stratum (below the Greenville bridge).

Table 7. Numbers of chinook salmon tagged and recovered during bi-monthly periods, 14 May - 15 September 1992.

${ }^{\text {a }}$ Includes Kiteen River.

Table 12. Radio-tag data used to estimate residence times of chinook salmon in Damdochax Creek, 1992. Fish that were recovered incidentally to carcass surveys are included; three males that died after leaving Damdochax Creek with known residence times of 18,21 and 23 days are excluded.

a
Arrival was determined by a fixed-station receiver positioned at the confluence of the Nass River and Damdochax Creek. A fish was considered to have entered Damdochax Creek when it moved upstream into the creek and was no longer recorded at the station.
b The fixed-station data indicated that fish (tag) No. 168 and No. 264 returned to the Nass River from Damdochax Creek for 3 and 5 days, respectively, before re-entering and committing themselves to Damdochax Creek.

${ }^{\text {a }}$ Numbers for reaches 4 and 5 were estimated from aerial counts using an assumed observer efficiency of $76 \%$ (this
b was based on the observer efficiency of the following survey which was conducted under similar survey conditions).
Reaches 1,2 and 3 were not surveyed by helicopter; total live count was estimated assuming reaches 4 and 5 contained $82 \%$ of the total number of chinook in the creek (based on aerial and ground surveys on September 10 ).

Table 15. Counts of holding and spawning chinook salmon as determined by aerial and ground surveys of Slowmaldo, Yaza, Sansixmor and Wiminasik creeks, 1992.

| System | Reach | Survey date | Survey type | Live count |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: |

## FIGURES

Figure 1. Map of the study area with locations of fixed-station receivers and the 34 chinook salmon spawning streams surveyed in 1992.

## Lower Nass River

Figure 2. Map of lower Nass River with locations of fishwheels and tangle net fishing sites.

Figure 3. Reach boundries and landmarks on Damdochax Creek.

Figure 4. Reach boundaries and landmarks on the Cranberry and Kiteen rivers.

## Lower Nass Tagging Sites

Figure 5. Spawning destinations of chinook salmon that were radio tagged on the lower Nass River during 1992 according to their date of capture.

## Grease Harbour

Cranberry Junction

Figure 6. Timing of movement of radio-tagged fish of different stocks by fixed-station receivers at Grease Harbour (FS1) and Cranberry Junction (FS3). The receiver at FS1 was not operating from 11:00 on 20 July to 6:00 on 24 July. See Figure 2 for site locations.

Figure 7. Timing of movement of radio-tagged fish of different stocks by fixed-station receivers at White River Junction (FS8) and Bell-Irving Junction (FS9). See Figure 2 for site locations.

Figure 8. Counts of adult chinook salmon from aerial surveys of Damdochax Creek. Top panel counts of live (all reaches) and dead (reaches $4 \& 5$ ). Bottom panel - counts of spawning chinook in different reaches.

Figure 9. Estimates of the number of chinook salmon passing the Kwinageese weir each day during 1992. Estimates for each day are based on bypass counts, index counts and extrapolation of index counts to counts from electronic counters.

## Damdochax Chinook Salmon

Figure 10. Comparison of aerial survey visual counts with total counts of radio-tagged fish for each survey of Damdochax Creek, 1992. Radio tags recovered during carcass examination surveys are not included after they are removed (see Table A-4 for recoveries).

Figure 11. Run timing of chinook salmon through the Meziadin fishway expressed as a cumulative proportion of the total fishway count, 1966-92 (bold line is 1992).

## APPENDICES

Table A-1. Fishing effort and numbers of chinook salmon caught in tangle nets and radio tagged on the lower Nass River, 13 May - 27 July 1992.
Effort is the number of hours that the net was in the water attempting to catch fish.

[^10]Table E-2. Estimated numbers of fish of each species that passed through the Kwinageese weir, 17 July - 23 September 1992.

Page 1 of 2

Table E-2. Estimated numbers of fish of each species that passed through the Kwinageese weir, 17 July - 23 September 1992.

a Shaded areas indicate periods when the electronic counter was not operating for which data were extrapolated using counts from adjacent days.
b Based on proporions calculated from index counts (presented in Table E-3).
Counts include sockeye tagged and sampled and chinook sampled that were released upstream without passing through counter. DV=dolly varden: WF=whitefish; RIB rainbow trout.

Table E-3. Species composition of fish that passsed through the Kwinageese weir based on index counts, 31 July - 27 September 1992.

| Period | Visual observations through electronic counter |  |  |  |  |  |  | Visual observations through bypass panel |  |  |  |  |  |  |

    ${ }^{3}$ P.O. Box 231, New Aiyansh, BC V0J 1A0

[^1]:    a Blanks indicate system was not surveyed (chinook presence unknown); P indicates chinook present but escapement not estimated.
    b Excludes years when the system was not surveyed.
    c Average of Total Nass estimated chinook escapements 1982-91.

[^2]:    ${ }^{\text {a }}$ Upper section is from Grease Harbour to the outflow of Tseax Slough; Middle section is from the outflow of Tseax Slough to the outflow of Zolzap Slough; Lower section is below the outflow of Zolzap Slough (primarily at or near Sandy River).
    An additional 3.4 h were spent in the Lower Stratum (Ginlulak and Fishery Bay) during this period.

[^3]:    a Includes partial and opportunistic surveys.
    No counts were made on 17 August and 10 September.
    $\mathrm{NA}=$ not applicable

[^4]:    ${ }^{\text {a }}$ Estimates for tributaries with $<4$ recaptures were derived by prorating (using the portion of radio-tagged fish tracked there) the escapement not accounted for by tributaries with $>3$ recaptures.
    ${ }^{\mathrm{b}}$ These estimates represent the escapement before sport fishery harvests on the Cranberry, Kiteen and Tchitin rivers.
    ${ }^{c}$ This category includes fish that did not reach their destination before the study ended.

[^5]:    ${ }^{\text {a }}$ Escapement after removals by all fisheries.
    ${ }^{\mathrm{b}}$ Based on the assumption that a stock's contribution to a mainstem harvest is proportional to its contribution to the gross escapement (from Table 20) for stocks in that fishery.
    ${ }^{\text {c }}$ Catch estimate derived from creel survey data (Bocking and English 1993a).

[^6]:    b Jacks were classified as all fish less than 72 cm ; fish smaller than 72 cm were too small to radio tag.
    Wheel 1 fished intermittently from 5 to 29 September; wheel 2 only fished for 3 d between 5 and 29 September.

[^7]:    ${ }^{\text {a }}$ Channel $11=149.520 \mathrm{MHz}$ and channels increase by .02 MHz (i.e. channel $12=149.540 ; 13=149.560 \mathrm{etc}$ )
    $\mathrm{NA}=$ not applied; ? = unknown

[^8]:    Counting group indicates the largest group of fish in which individual fish could not be counted.
    ${ }^{1}$ Carcasses were not systematically counted during aerial surveys.
    C These carcasses are not included in mark recapture estimates.

[^9]:    ${ }^{\text {a }}$ Reach 5: Damdochax Lake to Sansixmor Creek; reach 4: Sansixmor to Slowmaldo Creek; reach 3: Slowmaldo to 3 km downstream.

[^10]:    ${ }^{\mathrm{a}}$ Tag type: $\mathrm{R}=$ radio tag, $\mathrm{S}=$ spaghetti tag.
