## Canadian Technical Report of

Fisheries and Aquatic Sciences 2413

## Canadian Technical Report of Fisheries and Aquatic Sciences

Technical reports contain scientific and technical information that contributes to existing knowledge but which is not normally appropriate for primary literature. Technical reports are directed primarily toward a worldwide audience and have an international distribution. No restriction is placed on subject matter and the series reflects the broad interests and policies of the Department of Fisheries and Oceans, namely, fisheries and aquatic sciences.

Technical reports may be cited as full publications. The correct citation appears above the abstract of each report. Each report is abstracted in Aquatic Sciences and Fisheries Abstracts and indexed in the Department's annual index to scientific and technical publications.

Numbers 1-456 in this series were issued as Technical Reports of the Fisheries Research Board of Canada. Numbers 457-714 were issued as Department of the Environment, Fisheries and Marine Service Technical Reports. The current series name was changed with report number 925.

Technical reports are produced regionally but are numbered nationally. Requests for individual reports will be filled by the issuing establishment listed on the front cover and title page. Out-of-stock reports will be supplied for a fee by commercial agents.

## Rapport technique canadien des

 sciences halieutiques et aquatiquesLes rapports techniques contiennent des renseignements scientifiques et techniques qui constituent une contribution aux connaissances actuelles, mais que ne sont pas normalement appropriés pour la publication dans un journal scientifique. Les rapports techniques sont destinés essentiellement à un public international et ils sont distribués à cet échelon. Il n'y a aucune restriction quant au sujet; de fait, la série reflète la vaste gamme des intérêts et des politiques du ministère des Pêches et des Océans, c'est-à-dire les scences halieutiques et aquatiques.

Les rapports techniques peuvent être cités comme des publications complètes. Le titre exact paraît au-dessus du résumé de chaque rapport. Les rapports techniques sont résumés dans la revue Résumés des sciences aquatiques et halieutiques, et ils sont classés dans l'index annual des publications scientifiques et techniques du Ministère.

Les numéros 1 à 456 de cette série ont été publiés à titre de rapports techniques de l'Office des recherches sur les pêcheries du Canada. Les numéros 457 à 714 sont parus à titre de rapports techniques de la Direction générale de la recherche et du développement, Service des pêches et de la mer, ministère de l'Environnement. Les numéros 715 à 924 ont été publiés à titre de rapports techniques du Service des pêches et de la mer, ministère des Pêches et de l'Environnement. Le nom actuel de la série a été établi lors de la parution du numéro 925.

Les rapports techniques sont produits à l'échelon regional, mais numérotés à l'échelon national. Les demandes de rapports seront satisfaites par l'établissement auteur dont le nom figure sur la couverture et la page du titre. Les rapports épuisés seront fournis contre rétribution par des agents commerciaux.

#### Abstract

Bureau D., W. Hajas, N.W. Surry, C.M. Hand, G. Dovey, and A. Campbell. 2002. Age, size structure and growth parameters of geoducks (Panopea abrupta, Conrad 1849) from 34 loations in British Columbia sampled between 1993 and 2000. Can. Tech. Rep. Fish. Aquat. Sci. 2413: 84 p.

Samples of geoduck clams (Panopea abrupta, Conrad 1849) were collected from 34 locations throughout BC between 1993 and 2000. Clams were measured for total weight, shell length, shell weight and were aged. Summary statistics, age-frequency distributions and growth curves are presented by survey location and by geographic area. Relationships for shell length age, total weight - shell length, total weight - age and shell weight - age were calculated for all 34 samples and eight geographic areas.

Geoducks from Southern BC were generally smaller, younger and grew faster than geoducks from Northern BC. Possible causes for the smaller size and younger age in Southern BC are: 1-removal by the fishery of large old clams in Southern beds, 2- higher recruitment rates in Southern BC, or 3- pre-existing differences between Southern and Northern BC. Recent recruitment events were noted in several geoduck populations throughout BC and over a range of harvest histories. Variability in growth rates between and within regions suggests that the use of a single exploitation rate in the management of the BC geoduck fishery should be reviewed.

## RÉSUMÉ

Bureau D., W. Hajas, N.W. Surry, C.M. Hand, G. Dovey, and A. Campbell. 2002. Age, size structure and growth parameters of geoducks (Panopea abrupta, Conrad 1849) from 34 locations in British Columbia sampled between 1993 and 2000. Can. Tech. Rep. Fish. Aquat. Sci. 2413: 84 p.

Des échantillons de panopes (Panopea abrupta, Conrad 1849) ont été récoltés à 34 sites en Colombie-Britannique, de 1993 à 2000. On a mesuré le poids total, la longueur de la coquille, le poids de la coquille et l'âge. Pour chaque site et chaque région, les auteurs présentent des statistiques sommaires, des distributions de fréquences des âges et des courbes de croissance. Pour les 34 échantillons et les 8 régions, on a calculé des rapports entre la longueur de la coquille et l'âge, le poids total et la longueur de la coquille, le poids total et l'âge, et le poids de la coquille et l'âge.

En général, les panopes du Sud de la Colombie-Britannique étaient plus petites et plus jeunes que celles du Nord de la province, et la croissance de ces dernières était plus lente. Parmi les causes possibles de la taille plus petite et du plus jeune âge des individus vivant dans le Sud, on note : 1- la récolte de grosses panopes âgées dans les pêcheries des bancs du Sud, 2- des taux de recrutement plus élevés dans le Sud de la province ou 3- des différences préexistantes entre le Sud et le Nord de la Colombie-Britannique. Récemment, on a remarqué des recrutements dans plusieurs populations de panopes en Colombie-Britannique dans un éventail de profils antérieurs de récolte. La variation des taux de croissance inter- et intrarégionale indique qu'il faudrait réviser le taux d'exploitation unique pour la gestion des pêcheries de panopes dans cette province.

## 1. INTRODUCTION

The geoduck clam (Panopea abrupta, Conrad, 1849) is a large subtidal bivalve with a wide distribution that extends from Alaska to the Gulf of California in the Northeast Pacific (Quayle 1960). Geoducks are found in soft substrates (including mud, sand, silt and gravel), in water depths ranging from the intertidal to greater than 110 metres (Jamison et al. 1984). Geoduck harvesters prefer fishing in softer substrates like sand or mud and generally do not target geoducks found in harder gravel or shell-packed substrates. As well, harvest is focused on the stocks between 3 m and 20 m depth. Geoducks at greater depths, in hard substrate or in otherwise inaccessible areas occupy a form of refugia (Campbell et al. 1998a).

The geoduck fishery started in 1976 in British Columbia (BC) and has come to represent a valuable source of export for the province, with a 1999 fishery value of $\$ 33$ million (Hand and Bureau 2000). The geoduck fishery is managed on a precautionary, sustainable yield basis with annual harvest quotas calculated as one percent of the estimated virgin biomass. The exploitation rate is a conservative choice within the range of $0.75 \%$ to $2 \%$ suggested by age-structured yield modelling (Breen 1982). Values of input parameters for mortality and recruitment were estimated from a limited number of biological samples that were collected from Southern coastal areas (Breen and Shields 1983), where harvesting was concentrated in the first five years of the fishery. Since the early 1980's, the proportion of the coast-wide geoduck harvest that occurs in the North Coast has steadily increased.

Harbo et al. (1983) noted the need to estimate mortality rates of geoducks from more locations in BC. Campbell and Rajwani (1998) also noted the need for geoduck age samples to provide an indication of current recruitment levels. Orensanz et al. (2000) noted the urgent need for an extensive geoduck ageing program, with a broad geographic coverage, to address the uncertainties in stock assessment and to reduce risk in the management of the geoduck fishery. Bradbury and Tagart (2000) identified the direct estimation of mortality rates and recruitment of geoducks as research priorities.

Biological samples of geoducks have been collected during surveys, conducted throughout BC from 1993 to 2000, as part of the broader survey objectives of determining geoduck density, distribution and population structure. The goal of this paper is to present the results of analyses to determine age and size distributions, growth rates and morphometric characteristics of geoducks from 34 locations in BC, totalling 14,210 geoducks. Differences in morphometric and age parameters between regions of $B C$ were investigated by dividing the coast in eight geographic areas. Geographic area boundaries were based on broad management divisions, but further defined by oceanographic characteristics. Smaller scale differences in morphometric and age parameters were investigated by comparing sub-samples from within individual samples.

Further analysis of the sample data will lead to estimates of mortality, growth and recruitment characteristics for populations subjected to a range of exploitation rates. These will be presented in following reports where the parameter estimates for the purposes of yield modelling will be discussed.

## 2. METHODS

### 2.1. SURVEY SITES AND FIELD METHODS

Biological samples were collected during geoduck density surveys at 34 locations along the coast of BC between 1993 and 2000 (Figures 1 and 2, Appendix 1). The survey sites included a variety of fishing histories and management histories (Table 1 and Table 2) (Hand et al. 1998a, 1998b, 1998c; Harbo et al. 1992, 1993, 1995).

Survey design followed one of four survey types described in Campbell et al. (1998b) (Appendix 1). Early surveys (1993 through 1995) used a systematic transect placement with a random starting point protocol, where transects were spaced at regular intervals over large expanses of coastline, regardless of substrate type. Surveys conducted from 1996 to 2000 used a stratified random design, where geoduck beds were treated as strata and transects randomly placed within them. Survey locations for the latter surveys were based on harvest log maps, submitted by harvesters, that identified the locations of commercial harvest. A few large geoduck beds have been surveyed by placing transects within randomly selected grid squares that were over-laid on the bed.

Transects were assigned by Department of Fisheries and Oceans (DFO) personnel onto charts a priori, in order to reduce possible bias that might be encountered under field conditions. Secondary sampling units on transects consisted of $2 \times 5$ m quadrats surveyed systematically along the transects. Information collected at each quadrat included the number of geoducks observed, depth, substrate type, and dominant algae species. Field survey methods are described in detail in Hand and Dovey $(1999,2000)$ and Dovey and Hand (in prep).

Biological samples were collected on the last day of each survey. Approximately 500 clams were collected from a single site within the surveyed beds in 1993, 1994 and on four of the six surveys in 1995. In an effort to obtain a more representative sample, the protocol was modified for two of the 1995 surveys wherein five sub-samples of approximately 100 clams each were collected from within the surveyed beds. In 1996, sub-samples of approximately 150 clams were collected from three or four sites within the surveyed beds. Following a review of optimal sample sizes (Campbell and Rajwani 1998), the number of clams per subsample was reduced to 100 for samples collected in 1997 through early 2000. The protocol was modified again in September 2000 to again collect 150 clams per sub-sample site. Sample size was increased to account for losses due to shell breakage, tag loss and damage to soft body parts during sample collection, shipping and processing, and to provide a more representative sample for statistical analysis. Campbell and Rajwani (1998) suggested collecting approximately $10 \%$ more geoducks than the desired sample size to compensate for this loss.

Experienced commercial geoduck harvesters collected all samples. Prior to 1997, the majority of sampling locations were selected by choosing a randomly placed transect with suitable density, substrate and exposure. Suitable transect characteristics were analogous to a good commercial harvest location. From 1997 to 2000, the majority of sampling locations were selected by randomly choosing from eligible surveyed transects. A transect was considered eligible if it contained a 100 m section with enough geoducks to comprise a sub-sample. At each
sample location, divers attempted to sample the entire depth range surveyed and to sample nonselectively from the entire size range of geoducks. Divers used standard geoduck fishing commercial gear, i.e., surface supplied air (hookah) and a "stinger" (high-pressure water jet) to harvest the geoducks. The sampled geoducks were placed into dive bags, brought to the surface, and labelled with a unique identification number. Samples were then transported live to licensed processing plants.

### 2.2. LABORATORY MEASUREMENTS

### 2.2.1. Morphometric Measurements

-After the geoduck samples arrived at the processing plant, morphometric measurements were obtained by staff of Archipelago Marine Research Ltd. Draining time prior to weighing varied from several hours to two days, depending on shipping time from the harvest location. Total wet weight was obtained and shell length and width were measured using callipers while the animal was still in the shell. The geoducks were processed for body meat and the empty shells sent to the Pacific Biological Station for further processing. Shells were cleaned, dried, weighed and separated into individual valves prior to being again measured for length and width using callipers. Where a significant portion of a shell was broken, the shell weight was obtained by multiplying the weight of the intact valve by two. In cases where both shells were broken, the shell weight was not recorded. Shell length and width measured at the Pacific Biological Station were used for the analyses conducted in this paper, with the exception of the samples collected during the 1995 Duncan Island and Goletas Channel surveys. For these, shell dimensions measured at the processing plants were used because shell measurements were not obtained at the Pacific Biological Station.

### 2.2.2. Shell Ageing

Geoduck ageing methods followed those presented in Shaul and Goodwin (1982). The left valve of each geoduck was cut through the umbo using a water-cooled diamond blade rotary saw. If the left valve was damaged or lost, the right valve was used. The cut surfaces were polished dry using 400 and 600 -grit wet/dry diamond sandpaper mounted on rotating disks. The polished surface was then etched by applying a few drops of $1 \%$ hydrochloric acid solution for approximately one minute to reveal the annular rings, after which it was rinsed with distilled water. A peel of the etched surface was then made by applying a few drops of acetone and taking an impression of the annular rings on acetyl cellulose film (acetate). Each peel was then projected through a microscope and the number of annual growth rings counted and recorded. Shell preparation and age validation procedures are discussed in greater detail in Shaul and Goodwin (1982) and Noakes and Campbell (1992).

### 2.3. ANALYTICAL METHODS

Statistical analyses were completed using the statistics program, S-Plus 4.5 (Mathsoft 1997).

### 2.3.1. Shell Length - Age Relationship

The relationship between geoduck shell length and age was described using the von Bertalanffy, or LVB, growth model (von Bertalanffy 1938, in Quinn and Deriso 1999) (Equation 1).

$$
L(t)=L_{\infty}\left[1-e^{-\kappa\left(t-t_{0}\right)}\right]+\varepsilon_{1}
$$

Where:

- $L$ is length at age $t$
- $L_{\infty}$ is the mean length of very old geoducks
- $\kappa$ is a shape constant (Brody growth parameter)
- $t_{0}$ is a phase-variable
- $\varepsilon_{1} \sim N\left(0, \sigma_{1}{ }^{2}\right)$ is a normal variate

Initially, values for the independent parameters of Equation 1 were fitted simultaneously using maximum likelihood methods (Bain and Engelhardt 1991). For samples with many young geoducks, the fitted value of $t_{0}$ was between -1 and +1 . However, in samples where there were few young geoducks, the fitted-values of $t_{0}$ were too large (positive or negative) to be credible. The parameter $t_{0}$ was therefore set to zero for all the samples data sets, in order to fit the curves through the origin, and $L_{\infty}, \kappa$ and $\sigma_{1}$ estimated again.

### 2.3.2. Total Weight - Shell Length Relationship

An allometric growth model (Equation 2) (Quinn and Deriso 1999) was used to describe the relationship between total weight and shell length:

$$
W=\alpha L^{\beta *} e^{\varepsilon_{2}}
$$

Where:

- $W$ is the total weight of a geoduck
- $L$ is the shell length of a geoduck
- $\alpha$ and $\beta$ are parameters
- $\varepsilon_{2} \sim N\left(0, \sigma_{2}{ }^{2}\right)$ is a normal variate

By taking the natural log of Equation 2, the linear relationship was:

$$
\begin{equation*}
\log (W)=\log (\alpha)+\beta^{*} \log (L)+\varepsilon_{2} \tag{Equation 3}
\end{equation*}
$$

Originally $\alpha$ and $\beta$ were estimated as independent variables. However, a consistent relationship was observed between the estimated values of $\alpha$ and $\beta$ (Figure 3), which is described by:

$$
\begin{equation*}
\log (\beta)=0.5140-0.07231^{*} \log (\alpha) \tag{Equation 4}
\end{equation*}
$$

Since $\beta$ was a function of $\alpha$, Equations 3 and 4 were combined to give a weight-length relationship with one less site-specific parameter value to estimate. For each sample data set, maximúm likelihood methods were used to simultaneously estimate values for $\alpha$ and $\sigma_{2}$. Equation 2 indicates that, for a given length, the weight was assigned a lognormal distribution, therefore the estimated mean weight was larger than the weight that would be estimated if variability was ignored ( $\varepsilon_{2}=0$ ). Both upper and lower $95 \%$ confidence bounds were determined for the fitted total weight - shell length data.

### 2.3.3. Total Weight - Age Relationship

Combining the equations for the shell length - age relationship (Equation 1) and the total weight - shell length relationship (Equation 2), the equation for the total weight-age relationship was:

$$
W=\alpha^{*}\left(L_{\infty}^{*}\left(1-e^{-\kappa\left(t-t_{0}\right)}\right)+\varepsilon_{1}\right)^{\beta *} e^{\varepsilon_{2}}
$$

Equation 5

- $\varepsilon_{1} \sim N\left(0, \sigma_{1}{ }^{2}\right)$ is a normal variate
- $\varepsilon_{2} \sim N\left(0, \sigma_{2}{ }^{2}\right)$ is a normal variate

As mentioned previously, $t_{0}$ was set to zero and $\beta$ was treated as a function of $\alpha$. Maximum likelihood estimates were used to simultaneously estimate five model parameters. Two of the model parameters, $\sigma_{1}$ and $\sigma_{2}$, were used to describe variability.

Mean weight for a given age was calculated from 10,000 combinations of $\varepsilon_{1}$ and $\varepsilon_{2}$, representing equally probable ranges of values. First, 100 values of both $\varepsilon_{1}$ and $\varepsilon_{2}$ were generated corresponding to cumulative probabilities of $0.005,0.015,0.025, \ldots 0.995$. A value of $W$ was then calculated for each of the 10,000 combinations of $\varepsilon_{1}$ and $\varepsilon_{2}$. The mean value of $W$ approximates the average of the 10,000 values.

Bootstrapping was used to produce $95 \%$ confidence bounds for the mean weight. The 10,000 weight estimates were re-sampled with replacement 1,000 times and the mean calculated for each re-sample. Each re-sample was of size N , the size of the original sample over which the parameters were being estimated (e.g. individual survey data set or groupings of data over a geographic area). The 0.025 and 0.975 quantiles of the resample-means were used as $95 \%$ confidence bounds.

### 2.3.4. Shell Weight - Age Relationship

The shell weight - age relationships were first investigated using a model similar to that used in calculating the total weight - age relationships (Equation 5). The model was rejected, however, because it predicted shell weight would reach an asymptote, while data showed that shell weight continued to increase with age. An allometric model was therefore chosen to describe the shell weight - age relationship:

$$
S W=\gamma(A g e)^{\delta *} e^{\varepsilon_{3}}
$$

Where:

- $S W$ is the shell weight of a geoduck
- Age is the age of a geoduck
- $\quad \gamma$ and $\delta$ are parameters
- $\varepsilon_{3} \sim N\left(0, \sigma_{3}{ }^{2}\right)$ is a normal variate

By taking the natural log of Equation 6, the linear relationship was:

$$
\begin{equation*}
\log (S W)=\log (\gamma)+\delta^{*} \log (A g e)+\varepsilon_{3} \tag{Equation 7}
\end{equation*}
$$

The allometric model offered a better fit to the data as the model kept increasing with age and did not reach an asymptote over the domain of the data. Bootstrapping was used to estimate confidence bounds of the parameters.

### 2.3.5. Geographic Area Effects

The geoducks beds that are fished throughout the BC coast span a wide range of physical and oceanographic conditions and have experienced a variety of management regimes (Hand and Bureau 2000, Hand et al. 1998a, 1998b) and fishing histories (Table 1 and Table 2). Potential differences in growth parameters and morphometrics between regions, were investigated by first separating the data into geographic areas. Eight geographic areas were defined, based on differing fishery management history and/or oceanographic features. These include: Central Coast, North Coast, East and West Coasts of the Queen Charlotte Islands (QCI-East \& QCIWest), West Coast of Vancouver Island (WCVI), Area 24, Area 12 and Georgia Basin (Figures 1
and 2). In the geoduck fishery management plan, Northern BC is divided into three fishery rotation areas, each area being fished once every three years: Central Coast, North Coast and the Queen Charlotte Islands. For our purposes, the Queen Charlotte Islands were further divided into East and West, since the west coast is more exposed to weather and has been fished for fewer years (Table 2). Statistical Area 24, around Tofino, was separated from the rest of the WCVI because Area 24 has been fished annually, while rotational fisheries were in effect for the rest of the WCVI. The waters on the inside of Vancouver Island were broken down into Statistical Area 12 and Georgia Basin because they were managed differently (Hand and Bureau 2000, Hand et al. 1998a) and are subject different oceanographic conditions.

Survey samples were compared between geographic areas using a two-stage bootstrapping approach (Davison and Hinkley 1997). The following procedure, to generate the means and $95 \%$ confidence bounds of age, total weight, shell length and shell weight, was repeated one thousand times for each geographic area:

1. Survey data sets were re-sampled with replacement, where the size of each re-sample was equal to the number of survey data sets in the geographic area.
2. For each re-sampled data set, individual geoducks were re-sampled, with replacement, where the size of the re-sample was equal to the size of the original survey sample.
3. Averages were calculated for the re-sampled geoducks in the re-sampled survey. For any given calculation, some geoducks were used more than once and others were not used.

One thousand averages were thus generated for each geographic area. The 0.025 and 0.975 quantiles of the averages were used as the upper and lower $95 \%$ confidence bounds on the mean.

With this method, survey samples with more geoducks were weighted more heavily in the estimates of the means. Confidence bounds reflect the uncertainty that occurs when just a few surveys data sets wield disproportionate influence.

The same sets of 1,000 averages were used to establish confidence levels for differences in mean age, total weight, shell length and shell weight between geographic areas. Averages from one geographic area were compared against the averages from another area on a one-to-one basis. The fraction of times that the average from one geographic area was greater than the average from another was used as the confidence level that the mean from the first geographic area was greater than the mean from the second.

The same re-sampling that was used to establish confidence bounds on the means was also used to estimate confidence bounds on the parameters of the growth equations. Each time the geoducks were re-sampled, the model parameters were re-estimated.

### 2.3.6. Variability Within Geographic Areas

Analyses were also completed to determine if there was variability within geographic areas. Analysis of variance (ANOVA) was used to compare three sources of variability for age, total weight, shell length and shell weight: 1-variability between geographic areas, 2-variability between samples in the same geographic area; and 3-variability between geoducks in the same sample. Survey data sets were weighted according to the number of sampled geoducks. Subsamples were not considered in the analysis of variability within geographic areas.

### 2.3.7. Sub-Sample Analysis

Variations in age and morphometric parameters of geoducks may also occur on a small spatial scale due to differences from bed to bed or within a bed. For surveys where sub-samples were collected from different locations within a survey area, comparisons of mean age, total weight, shell length and shell weight between sub-samples were made to determine the variability of geoduck age and morphometric parameters on a small spatial scale. There were 22 surveys where sub-samples were collected. In these, there was an average of 3.2 sub-samples per biosample and 116 geoducks per sub-sample.

ANOVA was used to evaluate three sources of variability in the age of the geoducks: 1variability between biosamples, 2-variability between sub-samples of the same biosamples; and 3 - variability between geoducks in the same sub-sample. Geographic areas were not considered in this analysis.

A modelling exercise was also performed to predict how the sub-samples affected the estimated mean age, length and weight for a biosample. If a survey is balanced (same number of geoducks in each sub-sample), the standard error (SE) of the mean of a given parameter is:

$$
S E=\sqrt{\frac{\sigma_{\text {sub }}^{2}}{\text { Number_Subsamples }}+\frac{M S(\text { error })}{\text { Number_Animals }}}
$$

Equation 8

Where:

- $\sigma_{\text {sub }}^{2}$ was the estimated variance between sub-samples of the biosample.
- MS (error) was the estimated variance between geoducks in the same sub-sample.
- Number_Subsamples was the number of sub-samples in the biosample.
- Number_Animals was the number of geoducks in the biosample (combined subsamples).

Equation 8 showed that if the number of geoducks remained constant, then the estimated mean would be more accurate if more sub-samples per survey were taken. The existing data were used to estimate $\sigma_{\text {sui }}^{2}$ and MS(error) in order to predict how the number of sub-samples affected estimates of SE.

Each of the existing biosamples was treated as an unbalanced two-stage sampling design. The first stage was the sub-sample and the second was geoducks within the sub-sample. The data from all the applicable surveys were pooled together to get a larger sample size and better estimates of variability. The result was an unbalanced set of data.

The surveys were unbalanced and the expected sum of squares for a sub-sample ( $\operatorname{SSQ} Q(s u b)$ ) lead to the following approximation:

$$
E(S S Q(s u b))=E\left(\sum_{\text {survey subsumple }} n_{\text {sub }}\left(y_{\text {sub }}-y_{\text {survey }}\right)^{2}\right)
$$

Which can be approximated as:

$$
\sigma_{s u b}^{2} \sim \frac{S S Q(s u b)-M S(\text { error }) *(\text { Total_Number_of_SubSamples })}{\text { Total_Number_of_Animals }}
$$

Where:

- $n_{\text {sub }}$ was the number of animals in a sub-sample
- $y_{\text {sub }}$ was the mean value of a given parameter for a sub-sample
- $y_{\text {survey }}$ was the mean value for a biosample

For age: $\sigma_{s u b}^{2} \sim \frac{488982-879 * 68}{7883}=54.5$
For total weight: $\sigma_{\text {sub }}{ }^{2}=18771$
For shell length: $\sigma_{s u t}{ }^{2}=37.0$

Values of $\sigma_{s u b}{ }^{2}$ and MS(Error) estimated from available data were then input into Equation 8 and the values of number of sub-samples and total number of animals in a sample were changed to model their effect on the standard error.

## 3. RESULTS

### 3.1. AGE

A total of 12,848 geoducks could be aged out of the 14,210 that were collected, representing a $9.6 \%$ loss. Sample loss was due mostly to shell breakage during transport and/or processing, or to the loss of identification tags from shells.

Plots of age frequency distributions of survey data sets are shown in Figure 4. The oldest age recorded was 168 years from a geoduck from Tasu Sound, on the West Coast of the Queen Charlotte Islands (QCI-West, 2000). The youngest age recorded was 1 year, found at Hakai Pass
(Central Coast, 1998) and Comox (Georgia Basin, 1993). Mean age ranged from 14.5 years at Round Island (Georgia Basin, 2000) to 72.2 years at Hippa Island (QCI-West, 2000) (Table 3).

Overall, mean age of clams from Northern BC was higher than mean age of clams from Southern BC. Three of the six highest mean ages were from QCI-West (Hippa Island =72.2 yrs, Tasu Sound $=54.2$ yrs, Gowgaia Bay $=51.7$ yrs). The second, third and fourth highest mean ages were from the North Coast: West Aristazabal Island at 65.9 years, Moore Islands at 63.8 years and Principe Channel at 54.8 years. No sample from Northern BC had a mean age less than 30 years, whereas $50 \%$ of the samples from Southern BC had mean ages less than 30 years (Table 3). All samples from the Tofino region, Area 24 (Table 3) had a mean age under 30 years.

Many samples showed large proportions of young geoducks (Table 4, Figure 4). For seven of the 34 samples, more than $50 \%$ of geoducks were $\leq 20$ years, six of which were in Southern BC. Three of the seven samples had more than $50 \%$ of geoducks aged $\leq 10$ years. The site with the highest proportion of young clams was Round Island (2000) which had $78.0 \%$ of clams aged $\leq 10$ years. The Otter Pass sample was the only sample from Northern BC that showed more than $50 \%$ of clams $\leq 20$ years. For several samples, there was an underrepresentation of geoducks younger than 20 years old. The Selwyn/Dana/Logan Inlets sample showed the lowest proportion of young clams, only $2.5 \%$ of geoducks were $\leq 20$ years.

Year-class-strengths calculated for each sample and averaged by geographic area (Figure 5) showed an increase in recruitment between 1980 and the 1990's for most regions, most notably in Southern BC. The apparent drop in recruitment in the late 1990's was most likely an artefact caused by under-sampling of 1 to 5 year old clams, whose siphons may be too small to notice by divers harvesting the samples. Also, since samples were collected from several years during the 1990's, not all years are fully represented in all samples, especially for the late 1990's.

Only three samples, all in Northern BC, had more than $10 \%$ of clams older than 100 years (Table 4). Hippa Island (QCI-West) had the highest proportion of old clams, where $27.1 \%$ of geoducks were older than 100 years. Six samples showed no clams older than 100 years, three of which were from the Tofino area (Area 24). The others were in QCI-East and Price Island in the Central Coast.

When data were pooled by geographic area, QCI-West showed the highest mean age at 60.4 years, while the lowest mean age of 26.6 years was shared by Area 24 and the Georgia Basin (Table 5, Figure 6). Mean age in QCI-East, 42.6 years, was about 17 years lower than on the QCI-West. Mean age on WCVI (39.0) was about 12 years older than in Area 24.

ANOVA indicated that the mean age of geoducks was significantly different between both survey and geographic area (Table 6). Mean age was significantly higher in QCI-West than all other geographic areas except the North Coast (Table 7). All areas had significantly higher mean ages than Area 24 and the Georgia Basin.

### 3.2. TOTAL WEIGHT

Plots of total weight frequency distributions by year and survey location are shown in Figure 7. The heaviest clam sampled was $2,768 \mathrm{~g}$ at Gowgaia Bay (2000). Mean total weight ranged from 658.4 g at Seaforth Channel (Central Coast, 1995) to 1509.9 g at Gowgaia Bay (QCI-West, 2000) (Table 3). Although Seaforth Channel had the lowest mean total weight, the 1993 Comox sample showed the lowest mean shell length and shell weight, however no total weights were obtained from the sample (Table 3).

Mean weights tended to be higher for Northern BC than for Southern BC. Only three out of 20 samples in Northern BC had a mean total weight less than 800 g while seven out of 13 samples in Southern BC had a mean total weight less than 800 g .
-Cumulative percent frequencies of total weight showed that in the majority of samples, most clams were $\leq 1,500 \mathrm{~g}$ (Table 8 ). Only four samples showed more than $20 \%$ of clams to be $>1,500$ g: Gowgaia Bay (49.0\%), Elbow Bank (47.6\%), Burnaby Island (39.8\%) and Hakai Pass ( $29.2 \%$ ). The Thormanby Island sample was the only one to contain no geoducks heavier than $1,500 \mathrm{~g}$.

ANOVA indicated that the mean total weight of geoducks was significantly different between both survey and geographic area (Table 6). Data pooled by geographic area showed that the highest mean total weight, $1,112.6 \mathrm{~g}$, was found in Area 24 (Table 5, Figure 8) which had the lowest mean age. The lowest mean weight, 800.5 g , was found on the WCVI followed closely by the Georgia Basin at 819.4 g . The mean total weight in Area 24 was much higher than in the WCVI area, despite the fact that mean age of clams in Area 24 was younger.

Mean total weight was significantly greater in QCI-West, QCI-East and Area 12 than in WCVI and Georgia Basin (Table 7). Mean total weight was significantly greater in the Central Coast than in WCVI. Mean total weight was also significantly greater in QCI-East and Area 12 than in the North Coast. Although Area 24 had the highest mean total weight estimated, the mean total weight for Area 24 was not significantly different than that of other geographic areas due to its wide confidence bounds.

### 3.3. SHELL LENGTH

Mean shell length ranged from 120.5 mm at Comox (Georgia Basin, 1993) to 169.2 mm at Elbow Bank (Area 24, 1994) (Table 3). Elbow Bank had the second highest mean total weight. Gowgaia Bay (QCI-West, 2000), which had the largest mean total weight, had the second largest mean length at 164.6 mm and the largest clam found in the samples at 205 mm . As observed for the total weight, shell length of geoducks from Northern BC tended to be higher than that of geoducks from Southern BC. Mean shell length was larger than 140 mm in 11 of 20 samples from Northern BC while only three of 14 samples from Southern BC had a mean shell length larger than 140 mm .

ANOVA indicated that the mean shell length of geoducks was significantly different between both survey and geographic area (Table 6). Data pooled by geographic area showed that the highest mean shell length, 151.9 mm , was found in Area 24 (Table 5) followed by the four Northern BC geographic areas. The lowest mean shell length, 128.9 mm , was found in the Georgia Basin.

Shell length was significantly greater in QCI-East than all other areas except QCI-West, Area 24 and Area 12 (Table 7). All areas except WCVI had significantly larger shell length than the Georgia Basin. Mean shell length in QCI-West, QCI-East, Area 24 and Area 12 was higher than in WCVI.

### 3.4. SHELL WEIGHT

Mean shell weight ranged from 53.1 g at Comox (Georgia Basin, 1993) to 302.0 g at Gowgaia Bay (QCI-West, 2000). Elbow Bank (Area 24, 1994) had the second highest shell weight at 270.6 g (Table 3). The heaviest shell, 761 g , was found in the West Aristazabal Island sample (North Coast, 1996). Mean shell weight was generally higher in Northern BC than in Southern BC. Mean shell weight was greater than 150 g for 17 of 20 samples in Northern BC while only half (seven of 14) samples in Southern BC had a mean shell weight above 150 g .

ANOVA showed that the mean shell weight of geoducks was significantly different between both survey and geographic area (Table 6). Data pooled by geographic area showed that the QCI-West and QCI-East had the highest mean shell weights at 223.8 g and 222.3 g , while the Georgia Basin had the lowest mean shell weight at 108.5 g (Table 5).

All areas had a significantly higher mean shell weight than the Georgia Basin (Table 7). Mean shell weight in QCI-East was higher than that in the Central Coast, WCVI, Area 12 and the Georgia Basin. Mean shell weight at QCI-West, QCI-East, Central Coast and Area 12 was greater than in WCVI.

### 3.5. SHELL LENGTH - AGE RELATIONSHIP

Analyses of the shell length and age data, using the LVB growth model (Equation 1), showed that growth of geoducks in all survey sites was rapid in the first 10 years, followed by an extended period of slower growth (Figure 9). Variation in growth parameters between sample locations was noted (Table 9). The asymptotic length ( $L_{\infty}$ ) ranged from 127.7 mm at Seaforth Channel (Central Coast, 1995) to 169.7 mm at Elbow Bank (Area 24, 1997). There were no clear trends in $\mathrm{L}_{\infty}$ values between regions.

The Brody growth parameter (k) ranged from 0.1429 at Tasu Sound (QCI-West, 2000) to 0.4917 at Millar Channel (Area 24, 1997). Geoducks from Tasu Sound were therefore the slowest growing in terms of length, while those from Millar Channel were the fastest growing. Geoducks from Gowgaia Bay had the second highest $\mathrm{L}_{\infty}$ value but a low k value, indicating that geoducks reached a large maximum size but at a slow rate. WCVI and Area 24 showed some of
the fastest growth on the BC coast, with six of the highest eight k values from those regions. Area 24 alone had three of the four highest k values. Only Barkley Sound on the WCVI had a relatively low k value. Generally, growth tended to be faster in Southern BC than in Northern BC. Estimated k values were higher than 0.2500 for 12 of 14 samples in Southern BC while only four of 20 samples in Northern BC showed $k$ values above 0.2500 . Surprisingly, the second largest $k$ value ( 0.4318 ) was for Cumshewa Inlet (QCI-East, 1997). Geoducks sampled from Seaforth Channel had the second lowest growth rate and the lowest $\mathrm{L}_{\infty}$.

Pooling data by geographic area showed the highest $\mathrm{L}_{\infty}$ in Area 24 ( 161.0 m ) while the lowest value ( 135.2 mm ) was from the surrounding waters of WCVI (Table 10, Figure 10). $\mathrm{L}_{\infty}$ in QCI-East and QCI-West were very similar and relatively high (QCI-East $=147.5 \mathrm{~mm}$ and QCIWest=147.1 mm), however, geoducks from QCI-East grew faster than those from QCI-West. Growth rates were highest for WCVI, followed by Area 24. WCVI was therefore characterised by fast-growing clams that reached a small maximum size whereas Area 24 clams also grew fast but attained a large maximum size.

The $L_{\infty}$ at QCI-East, Area 24 and Area 12 was significantly higher than values in the Central Coast, WCVI and Georgia Basin (Table 11). $\mathrm{L}_{\infty}$ was also significantly higher in Area 24 than on the North Coast. QCI-West had a significantly lower k value than all other areas on the coast. Area 24 had a significantly higher $k$ than that of all areas except WCVI and QCI-East. The k value for WCVI was significantly greater than all other areas except Area 24, QCI-East and Georgia Basin. The k value for the Georgia Basin was significantly higher than that of QCIWest, North Coast and Central Coast.

### 3.6. TOTAL WEIGHT - SHELL LENGTH RELATIONSHIP

As mentioned previously, estimation of parameters of the allometric growth model (Equation 2, Figure 11) revealed a relationship between estimated values of $\alpha$ and $\beta$ such that values of $\beta$ decreased as $\alpha$ increased (Equation 4, Table 9, Figure 3). Given this relationship, the higher the intercept in the linear growth relationship, $\log (\alpha)$ in Equation 3, the lower the slope $\beta$. Growth curves from the sample data presented here ranged between two extremes. At one extreme, growth (weight gain per length increment) was initially slow, followed by a rapid increase of weight with length later in life (e.g. Hakai Passage 1998, Central Coast, Figure 11, Table 9). At the other extreme, the initial growth rate was high (steep initial slope) but the growth rate was more gradual over the remainder of the animal's life (e.g. Burnaby Island 1994, QCI-East, Figure 11, Table 9).

Unlike the Length - Age relationship, there were no clear trends in model parameter values for specific geographic regions for the Weight - Length relationship. However, there were differences between Northern and Southern BC. In Northern BC, 11 of $20 \alpha$ values were greater than 0.004000 while only five of $13 \alpha$ values in Southern BC were greater than 0.004000 . Conversely, eight of $13 \beta$ values in Southern BC were greater than 2.500 while only nine of $20 \beta$ values in Northern BC were greater than 2.500. In other words, Northern BC tended to have a higher initial growth rate while Southern BC tended to have a slow initial growth followed by a rapid increase in weight gain per length increment.

Once data were pooled by geographic area, a relationship between $\alpha$ and $\beta$ was still present. Area 24 had the lowest $\alpha$ and largest $\beta$ while Area 12 had the largest $\alpha$ and lowest $\beta$ (Table 10, Figure 12). Furthermore, when pooled by geographic area, the data showed a weak trend between $\alpha$ and the Brody growth coefficient k of the LVB growth model. Values of $\alpha$ decreased with increasing k so that the initial growth rate was faster in those geographic areas where overall growth, in terms of length vs. age, was slow. Conversely, geographic areas where overall growth (length vs. age) was fast were characterised by slow initial weight gain per length increment. In other words, in areas where growth (length vs. age) was fast, clams were light for their shell length while in areas where growth (length vs. age) was slow, clams were relatively heavier for their shell size. The differences mentioned above apply mainly to young clams, as curves with high $\alpha$ - low $\beta$ and those with low $\alpha$ - high $\beta$ tend to converge as clams increase in size.

- Values of $\beta$ were significantly larger in Area 24 than in all other areas except WCVI (Table 11). Values of $\beta$ for WCVI and the Georgia Basin were significantly larger than that of Area 12. Since $\alpha$ and $\beta$ values are inversely related, the opposite applies to $\alpha$ values. Values of $\alpha$ were significantly larger than that of Area 24 for all areas except WCVI. The $\alpha$ value for Area 12 was also significantly higher than that in WCVI and the Georgia Basin.

### 3.7. TOTAL WEIGHT - AGE RELATIONSHIP

Plots of Total Weight - Age relationships showed considerable variability between survey locations in both the growth rate and the maximum weight attained (Figure 13, Table 9). Each plot was fitted with the combined allometric total weight-shell length model and the LVB length-age model (Equation 5). Growth in total body weight was rapid in the first 10 to 20 years and then stabilised. Variability in growth rates was demonstrated by the range of slopes seen in the first 20 years on the graphs. Graphs with a steeper initial slope (e.g., Elbow Bank 1994, Figure 13) showed faster growth than those with lower initial slopes (e.g., Tasu Sound 2000, Figure 13). Variability in maximum total weight was demonstrated by differences in the level of the asymptotes on the graphs (Figure 13) and $\mathrm{TW}_{\infty}$ values (Table 9). The highest predicted mean total weight was $1,563.5 \mathrm{~g}$, for Gowgaia Bay (QCI-West, 2000) and the lowest predicted mean total weight was 680.8 g for Seaforth Channel (Central Coast, 1995). $\mathrm{TW}_{\infty}$ was directly related to $\mathrm{L}_{\infty}$ (Table 9). $\mathrm{TW}_{\infty}$ values varied within geographic areas but tended to be greater in Northern BC than in Southern BC. In Northern BC, TW ${ }_{\infty}$ was higher than 900 g for 15 of 20 samples while in Southern BC only seven of 13 samples had a $\mathrm{TW}_{\infty}$ greater than 900 g .

As for the Shell Length - Age relationships, the samples from Area 24 showed some of the fastest growth rates in terms of Total Weight - Age (Figure 13).

When data were pooled by geographic area, the highest $\mathrm{TW}_{\infty}$ calculated, $1,268.3 \mathrm{~g}$, was for Area 24 (Table 10, Figure 14). The lowest TW $\infty$ calculated, 805.3 g , was for WCVI. Geoducks from Area 24 grew faster and to a larger size than those from WCVI. The TW $\infty$ was about the same for QCI-East and QCI-West ( $1,059.2 \mathrm{~g}$ and $1,042.2 \mathrm{~g}$ respectively), however, the growth rate was faster on QCI-East so the maximum size was reached at a younger age.

The $\mathrm{TW}_{\infty}$ values for QCI-East, Area 24 and Area 12 were significantly larger than those in the North Coast, WCVI and Georgia Basin (Table 11).

### 3.8. SHELL WEIGHT - AGE RELATIONSHIP

An allometric model was used to fit the shell weight to the age data for each survey and geographical area (Table 12 and Table 13, Figure 15). The model provided a good fit to the data for geoducks above 5 years of age. For geoducks under 5 years, the model tended to overestimate the shell weight for a given age. The over-estimation of shell weight of clams less than 5 years was best seen in the Georgia Basin data (Figure 16) where most of the clams under 5 years of age were found.
-Estimates of $\gamma$ and $\delta$ on a by-survey basis indicated that $\delta$ tended to decrease as $\gamma$ increased (Table 12), that is, as the intercept ( $\gamma$ ) on the $\log$ (Shell Weight)-log(Age) graphs increased, the slope ( $\delta$ ) decreased. Estimates of $\gamma$ and $\delta$ varied within and between geographic areas. There were no clear trends in $\gamma$ and $\delta$ between Southern and Northern BC. However, six of seven samples from the Georgia Basin and Area 12 showed a $\delta$ value greater than 0.600 while only seven of 20 samples from Northern BC and no samples from the WCVI and Area 24 had $\delta$ values greater than 0.600 . Elbow Bank (1994) had the highest $\gamma$ and lowest $\delta$ while Comox (1993) and Seaforth Channel (1995) shared the lowest $\gamma$ and the highest $\delta$.

The same trend for $\delta$ to decrease with increasing $\gamma$ was present in the by-geographic area estimates (Table 13). The trend had exceptions, most notably Area 24 which had both a high $\gamma$ and $\delta$ meaning that shell weight in Area 24 was generally high for any given age compared to the other geographic areas. Values of $\gamma$ were significantly higher in Area 24 than in the North Coast, Central Coast, Area 12 and Georgia Basin (Table 14). Values of $\gamma$ were also significantly higher on WCVI than in the Central Coast, Area 12 and Georgia Basin (Table 14). Values of $\gamma$ in QCIEast were higher than in the Central Coast and Area 12. Values of $\delta$ were higher in the Central Coast than in the QCI-East and West and WCVI. Values of $\delta$ in Area 12 were significantly higher than in the QCI-West and WCVI.

### 3.9. SUB-SAMPLE ANALYSIS

ANOVA indicated that there were significant differences in age, total weight, shell length and shell weight between both the samples and sub-samples (Table 15).

Analyses to determine if taking sub-samples was advantageous showed that the standard error around the estimated means could be decreased by increasing the total number of geoducks sampled or, by increasing the number of sub-samples in the biosample (Table 16). There were however, diminishing-returns effects to increasing the number of sub-samples, i.e., each additional sub-sample gave less benefit than the previous one.

## 4. DISCUSSION

This examination of geoduck age data is the largest of its kind in the literature. Seven studies of geoduck age-structure from BC and Washington (WA) have previously been published, in which a total of 7,251 geoducks were aged (Table 1 in Orensanz et al. 2000). Four studies provided parameter estimates of the LVB growth model from a total of 21 sites in BC and WA (Andersen 1971, Hoffmann et al. 2000, Noakes 1992, Noakes and Campbell 1992). The current study included 12,848 geoducks from 34 locations in BC. LVB growth parameters were estimated for all locations sampled.

### 4.1. AGE

The estimated maximum age of geoducks in BC has increased from 146 years (Harbo et al. 1983) to 168 years. Mean ages from the current study span a wider range ( 14.5 years to 72.2 years) than previous studies (Goodwin and Shaul 1984, Harbo et al. 1983, Breen and Shields 1983, Fyfe 1984, Noakes and Campbell 1992) (Table 17), which is likely a function of the larger number of samples considered, the more extensive geographic range of these samples and the longer fishing history of at least some of the sample locations.

There is strong evidence that the commercial fishery acts to remove the older age-classes that have accumulated in a population over time. The proportion of samples comprised of older clams and the mean age was generally higher in Northern BC than in Southern BC; Southern BC beds have been fished longer (Table 2). Area 24 and the Georgia Basin, the two geographic areas with the lowest proportion of older clams, have longer fishing histories than the rest of BC, and QCI-West, with the highest mean age, is the region that has been fished the least. Thormanby Island is one site in Georgia Basin where fishing pressure has been very low due to the poor quality of the geoducks; the sample there showed a higher proportion of older clams than other areas in the Georgia Basin. Further evidence of the effect of harvest on populations is the decrease in mean age in locations where previous estimates are available. A sample collected from Comox Bar in the Georgia Basin in 1981 had a mean age of 46.1 years, while the sample collected in 1993 had a mean age of only 19.2 years (Table 3 and Table 17). Similarly, two sample locations on the West Coast of Vancouver Island, Kyuquot and Elbow Bank, showed decreases in mean age of 18.8 years and 5.8 years, respectively, over periods of 17 and 13 years.

Some sites in Northern BC, however, show low proportions of older clams, despite relatively light fishing pressure. Furthermore, samples collected from virgin beds in Northern BC (Tasu Sound, Principe Channel and Moore Is.) had mean ages within the range of Northern BC samples from fished areas. Possible impacts of the fishery on age-structure in Northern BC beds were therefore not evident at this time. The Northern BC samples from virgin beds (Table 3) are the most comparable to the early 1980's Southern BC research samples (Table 17). Comparing samples from virgin beds from Northern and Southern BC shows that mean age tended to be higher in Northern BC. This suggests that differences in mean age between Northern and

Differences in mean age between samples are due also to varying proportions of younger clams. While recognising that high proportions of young clams in a sample could merely be a result of the absence of older clams, many samples display what appears to be evidence of strong recent recruitment. Over half of the geoducks in the samples from Comox (1993 and 1998), Round Island, Kyuquot, Millar Channel, Yellow Bank and Otter Pass are younger than 20 years old. These animals would have recruited to their respective populations since the beds began to be commercially exploited. Year-class-strength graphs also showed increased recruitment since 1980. Estimated densities of newly recruited geoducks in the area of sample collection (from Table 4 and Appendix 1) are significant in comparison to the estimated virgin densities from the same bed:

| Area | Year | Recruit Age | Recruit Density geoducks $/ \mathrm{m}^{2}$ | Virgin Density |  |
| :---: | :---: | :---: | :---: | :---: | :---: |
|  |  | Cut-off |  | geoducks $/ \mathrm{m}^{2}$ | Source |
| Comox | 1993 | 10 | 0.30 | 0.45 | Hand and Bureau 2000 |
|  | 1998 | 10 | 0.15 | 0.45 | Hand and Bureau 2000 |
| Round Island | 2000 | 10 | 0.30 | 0.99 | Unpublished data |
| Millar Channel | 1997 | 10 | 0.82 | 1.96 | Hand and Bureau 2000 |
| Yellow Bank | 1997 | 10 | 0.41 | 3.05 | Hand and Bureau 2000 |
| Otter Pass | 1996 | 20 | 2.20 | 2.68 | Hand and Bureau 2000 |

The Round Island bed was closed after the 1994 fishing season due to its heavy harvest history and, in $2000,26.7 \%$ of geoducks were $\leq 5$ years and thus had recruited to the bed after it was closed to fishing. All these beds are popular fishing locations with relatively long harvest histories. This suggests that harvest activity does not have the negative effect on recruitment that was suggested by Goodwin and Shaul (1984) and may even enhance it, provided there is a source of larvae. Geoduck larvae can spend up to 6 weeks in the water column (Goodwin et al. 1979) so recruitment to heavily harvested beds may come from other populations.

Past studies have largely concluded that geoduck recruitment rates were low (Breen and Shields 1983, Fyfe 1984, Godwin and Shaul 1984, Harbo et al. 1983, Noakes and Campbell 1992, Sloan and Robinson 1984), although it was acknowledged that it may be partly explained by sampling bias. The review of the published studies to 2000 conducted by Orensanz et al. (2000) further suggested that recruitment has been decreasing over the last 60 years, many years before the fishery and hence due to other forces. The results presented here indicate that many geoduck populations along the BC coast have experienced relatively good recruitment events in recent years in beds over a range of harvest histories.

Of particular note is the strong appearance of the 1988 year-class in samples throughout the coast in both lightly fished and heavily fished populations. This synchrony of recruitment over large areas of the BC coast would imply that periodic conditions favourable to larval settlement and survival are widespread. In most of the age frequencies examined, the appearance of prominent modes suggests that recruitment is not consistent from year to year, but rather undergoes periodic pulses.

### 4.2. WEIGHT AND SIZE DISTRIBUTIONS

Overall, samples from Northern BC contained higher proportions of heavier animals, which is likely linked to the wider age-distribution discussed earlier. The distributions of total weight can be quite variable within geographic regions; Gowgaia Bay has a very wide distribution while Hippa Island has a relatively tight distribution of total animal weights, despite the wide range in ages found at Hippa.

There was a high degree of variability in the size of animals between regions of the coast and, generally, geoducks from Northern BC tended to be larger than those from Southern BC, with the exception of Area 24. As well, large differences existed between samples within some geographic regions. For instance, the mean weight of animals from Gowgaia Bay is approximately twice that of clams from Hippa Island just to the north on QCI-West, but approximately the same as Elbow Bank in Area 24. Comox Bar in Georgia Basin and Seaforth Channel in the Central Coast have the smallest clams on the coast. There is especially high variability of total weight within Area 24. Elbow Bank geoducks were close to the largest and heaviest on the coast while Millar Channel and Yellow Bank animals, less than nine km away, were similar to the average size for the rest of the West Coast of Vancouver Island. Breen and Shields (1983) found similar results in their study of geoduck populations from BC, where their sample from Elbow Bank had the highest and second highest mean length and weight, respectively, of five sites investigated. Harbo et al. (1983) also reported similar results in a study of 10 commercial geoduck samples where the two highest mean lengths were from Elbow Bank and another bed in Area 24.

Goodwin (1976) found differences in mean shell length of geoduck samples from 24 locations in Puget Sound, WA. Goodwin and Pease (1991) also found differences in mean total weight and shell length of geoducks between four geographic areas in Puget Sound which, though following a decreasing trend with increasing latitude, they attribute to different local conditions.

Mean geoduck weights, estimated from commercial harvest log data, showed little trend with geographical area. Geoducks harvested from QCI-East were the heaviest ( $1,292 \mathrm{~g}$ ) followed by Area 12 ( 1,158 g), QCI-West, North Coast, Central Coast, Area 24, Georgia Basin and the West Coast of Vancouver Island (1,054 g) (Hand and Bureau 2000, QCI unpublished data).

Geoducks from the Georgia Basin were generally smaller than geoducks from other areas on the coast. A study of geoduck market samples, collected between 1981 and 1995, found that geoducks from the Inside Waters of Vancouver Island were smaller than geoducks from the West Coast of Vancouver and geoducks harvested from the North Coast were the largest (Burger et al. 1998). However, no published studies have followed trends in market weights of geoducks over time for BC. Such studies would help determine to what extent the lower geoduck sizes observed in the Georgia Basin are a result of the fishery.

### 4.3. GROWTH

Growth was similar to that reported in other studies (Andersen 1971, Goodwin 1976, Breen and Shields 1983, Harbo et al. 1983, Goodwin and Shaul 1984, Noakes and Campbell 1992, Hoffman et al. 2000). Geoducks shell length and total weight increases rapidly from settlement to 10 years, growth may continue at a considerably slower rate for the next 10 years and ceases thereafter except for a gradual thickening of the shell. Rapid growth in early life allows geoducks to attain sufficient size and thus a refuge depth in the sea floor that is safe from predators. The end of rapid growth and burrowing coincides with the beginning of annual reproductive activity (Sloan and Robinson 1984).

Growth rates varied considerably between locations, as observed in previous studies (Harbo et al. 1983, Goodwin and Shaul 1984, Noakes 1992, Hoffmann et al. 2000). Overall, growth rates tended to be higher in Southern BC than in Northern BC, although there were many exceptions. Growth in 11 sites in Puget Sound (Hoffmann et al. 2000) had a similar range of asymptotic length as BC data, but lower k values. This may indicate faster growth in BC or it may be due to differences in methodologies. Their study used measurements of inter-annular growth increments for individual clams from the acetate peels of the shell sections.

There was little relationship between the growth rate and the maximum size reached. Both fast-growing and slow-growing clams can reach large sizes (e.g. Elbow Bank and Gowgaia Bay, respectively), and fast and slow-growing clams can plateau at small sizes (e.g. Winter Harbour, Seaforth Channel). Apparently, the factors responsible for fast growth are not the same as those that control the maximum size reached.

Differences in growth rate between locations may be caused by a variety of factors. Breen and Shields (1983) found a relationship between mean size of the population and its exposure to surge, where the smallest clams were found at the area of highest exposure. In our study, growth rates were lower in populations on the QCI-West, where exposure to ocean swell is generally higher, than on the more protected QCI-East, although there was no such relationship with the maximum size reached (which were highly variable). High wave activity from storms can result in geoducks retracting their necks below the substrate surface (Campbell et al. 1996, 1998c, Hand et al. 1998d), which in turn reduces the feeding time. Growth would logically be lower under such conditions.

Although Goodwin and Pease (1991) found no relationship between mean geoduck size and density, our results suggest that geoducks from very dense populations may be smaller than those in less dense populations. In the QCI-West, geoducks sampled from Hippa Island with an average density of $3.43 / \mathrm{m}^{2}$ were small compared to those from Gowgaia Bay with and average density of only $0.75 / \mathrm{m}^{2}$, although their growth rates were similar. Similarly, the clams from Millar Channel and Elbow Bank had fast growth rates, but were much smaller in the former location where densities were approximately three times higher. Dundas Island is another example where a relative fast growth rate is associated with small animal sizes and high densities.

Goodwin and Pease (1991) found a link between sediment type and mean geoduck length, where clams were larger in sand and sand/mud, than in mud or pea gravel. They also found higher densities in sand than in mud or gravel. Likely, the mechanisms are inter-related, in that local water currents determine both particle size in soft sediments and the amount of planktonic material that flows past the clams' inhalent siphon. Goodwin and Pease (1987) suggested that growth and final size were dependent on local primary productivity of phytoplankton and volume of food-bearing currents. Hoffmann et al. (2000) found growth to be greatest in sites that are subject to intermediate tidal flow. As well, changes in mean annual temperature could be associated with shifts in annual geoduck growth (Noakes and Campbell 1992).

The relationship found between $\alpha$ and $\beta$ values of the allometric growth model implies that geoducks from different locations experienced different growth patterns. The growth patterns ranged from fast initial growth, in terms of weight gain per length increment, with a growth rate that increased little with size, to slow initial growth with a pronounced increase in growth rate with size. For geoducks in the former case, body weight increased at a relatively constant rate and the rate did not increase much with size. For geoducks in the latter case, at first, body weight increased slowly as the shell grew, producing "skinny" clams with long shells, followed by a period of rapid increase in body weight. With data pooled by geographic area, Area 24, WCVI and the Georgia Basin showed the three lowest initial growth rates $\alpha$ and three the largest $\beta$ values. These regions also exhibited some of the fastest growth rates in the length age relationships (high k values). A trend for $\beta$ to increase with k was also present in the bysurvey analyses although with many exceptions. Geoducks whose growth in shell length (vs. age) was fast therefore gained relatively little weight per length increment until a time where the rate of weight gain increased greatly. If burying depth is related to shell length then investing more energy in shell growth may allow geoducks to attain a depth refuge from predators earlier in life than geoducks with slow shell growth. Geoducks with fast initial shell growth could therefore be expected to invest less energy in weight gain until such time as the depth refuge is reached and shell growth starts to slow.

Visual examination of data often showed that shell weight was the variable that had the closest relationship with age. Unlike shell length or total weight which reach an asymptote, shell weight continues to increase with age due to the shell's thickening rather than growth in length (Harbo et al. 1983, Goodwin and Shaul 1984, Sloan and Robinson 1984). A linear model of the log-transformed data fitted the data well for geoducks above 5 years of age (Figures 15 and 16). Despite the fit, variability in estimates of $\gamma$ and $\delta$, both within and between geographic areas, suggests that shell weight may be of little use as a predictor of age, unless applied only on a small spatial scale. Fyfe (1984) arrived at the same conclusion when describing shell-thicknessindex to age relationships for three sites in the Tofino area.

The results showed that differences in mean age, total weight, shell length and shell weight were sometimes present between sub-samples of a given survey location. The use of subsamples is thus warranted to get a better representation of mean age, weight and length of geoducks from a general area. The analyses showed that increasing the number of sub-samples taken on a survey may be desirable since it decreased the standard error of mean age, weight and length estimates. However, logistical considerations in the field would probably prevent taking
more than five sub-samples per area due to the time required to change sampling locations (retrieve diver hoses and boat anchor, move boat to new location and re-deploy diver hoses). Furthermore, since there are diminishing returns to increasing the number of sub-samples collected, taking more than five sub-samples per survey would provide little additional benefit considering the time costs associated. Campbell and Rajwani (1998) recommended taking two samples of 100 geoducks from two sites within a bed, at two beds, for a total of 400 geoducks. The current practice of taking samples of 150 geoducks from three sites (total 450 clams) within a survey area is probably adequate as a compromise between optimal sampling and logistical considerations.

### 4.4. CONCLUSIONS

- Geoducks from Southern BC tended to be younger and smaller than geoducks from Northern BC. Possible causes for these differences are: 1) removal of old, large clams from Southern BC beds with a longer fishing history; 2) different growth patterns in different regions; or 3) more recruitment in Southern BC. Early Southern BC data suggests that mean age and size have decreased in at least some areas and supports the hypothesis that the fishery has removed old age classes from some populations. Some data support the second hypothesis in that, generally, growth was faster and maximum size smaller in Southern BC so that the maximum size was attained at a younger age than in Northern BC. Also, data from virgin beds indicated higher mean age in Northern BC samples suggesting differences in mean age between Southern and Northern BC may have been present before the fishery. Hypothesis-3 was also supported as data suggested higher recruitment in Southern BC. Therefore, the cause of the younger mean ages and smaller sizes observed in Southern BC is probably a combination of all three factors.

Geoduck market weight data should be re-analysed to look at trends in landed weights over time for different regions of the coast to determine the effect of the fishery on landed weights for different regions. Re-survey of certain sites may also help separate random effects from the effects of harvest on mean size and age of geoducks.

The Tofino area (Area 24) was the region of the coast that showed the fastest growth in terms of length - age, the highest mean length, total weight and lowest mean age. Area 24 therefore appears to be the most productive area on the BC coast. Area 24 is characterised by large shallow sandy banks and high tidal currents, which may be conducive to high productivity. Further analyses of existing data should be conducted to determine the effects of geoduck density, substrate, current regime, exposure and depth on the growth parameters estimated in the current study.

Significant differences in growth rates between and within regions of the BC coast were shown. The use of a single exploitation rate applied to the BC coast in the management of the fishery may therefore be inappropriate. Hoffmann et al. (2000) had similar results in Washington State and suggested that managers use the lowest $k$ value (conservative approach) for a region or that a study with a sampling plan designed to yield unbiased regional estimators be conducted.

Data presented here did not show obvious negative effects of geoduck harvesting on recruitment of geoducks to fished beds. However, harvesting appears to remove larger and older geoducks from the population, which may impact the reproductive output of the population. Ongoing sampling of geoducks for age determination should be continued to monitor trends in recruitment.

A recent review has suggested that an extensive geoduck ageing program with broad geographic coverage was needed to reduce risks and uncertainties in the management of geoduck fisheries (Orensanz et al. 2000). The current study is a first step in the analysis of geoduck age data from BC. Mortality rates and recruitment mechanisms have been identified as research priorities for geoducks because the mortality rate is the parameter with the most influence on yield modelling (Bradbury and Tagart 2000). Harbo et al. (1983) also identified the need for mortality rate estimates based on a wide sample of geoduck populations. These topics will be the focus of further analyses performed on the data presented in the current paper and are to be published in future reports.

## ACKNOWLEDGEMENTS

We would like to thank the Underwater Harvester's Association for its ongoing financial support and participation in the sampling of geoducks during biological surveys. The Haida Fisheries Program, Kitasoo Fisheries Program, Kwakiutl Territorial Fisheries Commission, Heiltsuk Fisheries Program and the Cowichan Tribes participated in various field surveys and provided logistical support. Bill Thomson cut and polished shells. Kathy Southey, Jennifer Nash and Judy McArthur completed the geoduck ageing. Norm Olsen and Al Cass provided assistance with statistical analysis and S-Plus programming. Ian Murfitt provided GIS support. Paul Breen provided us the 1980 and 1981 data. Georg Jorgensen assisted with database preparation. Brian Krishka and Graham Gillespie reviewed the manuscript.

Table 7: Confidence levels that mean values for each variable are different between geographic areas. Values represent the confidence level that the geographic area in the column has a higher mean than the area in the row. Values $\geq 0.95$ are significantly different and are indicated in bold print.

| Georgia Basin | 13.14 | 0.6448 | 0.5564 | 1644 |

Table 14: Confidence levels that model parameters for the Shell Weight - Age relationships are different between geographic areas. Values represent the confidence level that the geographic area in the column has a higher mean than the area in the row. Values $\geq 0.95$ are significantly different and are indicated in bold print.

| Parameter | Geographic Area | QCl <br> West | QCI East | North Coast | Central Coast | Area 24 | West Coast | Area 12 | Georgia Basin |

[^2]
[^0]:    ${ }^{1}$ Underwater Harvesters Association, PO Box 39005,3695 W $10^{\text {th }}$ Ave, Vancouver, BC, V6R 4P1

[^1]:    ** From Noakes 1992. Note that for some locations it is unclear if the estimate is for the 1980, 1981 or 1982 data set, or if data sets were combined.

[^2]:    Number of geoducks aged reported on a per-survey basis only, numbers were not broken down to the sub-sample level. $\mathrm{Sh}=\mathrm{Shell}, \mathrm{M}=\mathrm{Mud}$ ${ }^{2}$ Substrate: $\mathrm{B}=$ Boulders ( $>30 \mathrm{~cm}$ ), $\mathrm{C}=$ Cobble ( $10-30 \mathrm{~cm}$ ), $\mathrm{Gr}=$ Gravel $(2-10 \mathrm{~cm}), \mathrm{PGr}=$ Pea Gravel ( $4 \mathrm{~mm}-2 \mathrm{~cm}$ ), $\mathrm{S}=\mathrm{Sand}, \mathrm{Sh}=\mathrm{Shell}, \mathrm{M}=\mathrm{Mud}$ ${ }^{3}$ Average Depth: depths with an asterisk are not corrected for tide height ${ }^{4}$ Survey Design:
    1 Systemati
    1 Systematic: Transects are systematically placed along the shore in the area to be surveyed. The first transect is randomly placed, and subsequent transects placed at a
    predetermined distance (distance varies depending on bed size). Geoduck counts may be recorded within all consecutive quadrats along each transect, or after sampling
    quadrat number 1, every qth (e.g. every 2nd, 3rd or every 4th) quadrat along a transect is sampled. The interval between sampled quadrats may vary within a given bed or site. surveying. A transect(s) is placed in each of the selected squares and the quadrats sampled as in survey design 1. 3 Three-Stage Sampling: Transects are randomly placed along the shore in the area to be surveyed. Each transect is sectioned into blocks that can accommodate q quadrats per block, e.g. a block would be 20 m long for 4 quadrats ( 5 m quadrat length). Geoducks are counted in one quadrat randomly located in one of the q possible quadrats in 4 Two-Stage Sampling: Transects are randomly placed along the shore in the area to be surveyed. After sampling quadrat number 1 , every qth (e.g. every $2 n d, 3 r d$ or every 4 th) quadrat along a transect is sampled. The interval between sampled quadrats may vary within a given bed or site.
