ABSTRACT

Caissie, D. 1991. The Importance of Groundwater to Fish Habitat: Base Flow Characteristics for Three Gulf Region Rivers. Can. Data Rep. Fish. Aquat. Sci. 814: 25p.

The importance of groundwater to fish habitat and productive capacity of streams is discussed in this report through a presentation of groundwater related data for three Gulf Region rivers. Groundwater flow data were calculated for the Wilmot River in Prince Edward Island, the Kouchibouguac River in New Brunswick, and the Ste. Genevieve River in Newfoundland using the daily discharge hydrographs. The base flow recession constant, which is an indication of groundwater discharge during periods of no precipitation, was calculated for selected recession periods. An estimate of groundwater discharge (base flow) was also calculated using a graphical hydrograph separation technique. From the graphical hydrograph separation technique. From the graphical hydrograph separation technique.

RÉSUMÉ

Caissie, D. 1991. The Importance of Groundwater to Fish Habitat: Base Flow Characteristics for Three Gulf Region Rivers. Can. Data Rep. Fish. Aquat. Sci. 814: 25p.

L'importance des eaux souterraines pour l'habitat du poisson et la capacité productive du cours d'eau est discutée dans ce rapport par une présentation de données reliés aux eaux souterraines de trois rivières de la région du golfe. Les données des eaux souterraines ont été calculées à l'aide des hydrogrammes des débits journaliers pour la rivière Wilmot à l'Ile-du-Prince-Edouard, la rivière Kouchibouguac au Nouveau-Brunswick et la rivière Ste. Genevieve à Terre-Neuve. Les constantes de récession de l'écoulement de base, indiquant le débit des eaux souterraines pour de périodes sans précipitation, ont été calculées pour des périodes de récession choisies. Une estimation du débit des eaux souterraines (écoulement de base) a également été calculée en utilisant une méthode graphique de séparation des hydrogrammes. A l'aide de la méthode graphique de séparation des hydrogrammes, les débits de base mensuels et le rapport du débit de base sur le débit total ont été calculés.

INTRODUCTION

Fish habitat and the productive capacity of streams is influenced by many hydrological phenomena such as floods, droughts, baseflow, and streamflow variations. For example, Frenette et al. (1984) showed the importance of discharge to young Atlantic salmon (Salmo salar) by correlating the number of fish to different flows. The importance of the basin's hydrology to the stream's productivity was also reflected in another of Frenette's studies, in which he discussed the effects of floods and droughts on a population of Atlantic salmon (Frenette 1987). Streamflow or river discharge is one component of the hydrologic cycle which strongly influences the fisheries resource. Streamflow can be further subdivided into the following components: surface runoff, interflow, channel precipitation, and groundwater flow. The groundwater flow (or base flow) has proven to be very important for fish and their habitats (Benson 1953). Groundwater flow tends to stabilize stream discharge and also reduces extreme water temperatures by providing a warmer temperature regime during winter and cooler temperatures during summer. Warmer stream temperatures during winter are especially favourable for overwintering fish (Cunjak and Power 1986) and eggs (Cunjak et al. 1986). In summer, stream temperature tends to be cooler because of groundwater influx to the channel. The cooler stream temperature has a better capacity for dissolved oxygen, and maintains suitable habitat conditions, even during periods of extremely high air temperature. Therefore, a groundwaterfed stream is more stable, less flashy, and more productive (Bovee 1982; Edwards et al. 1979).

To understand the effects of groundwater flow on fish habitat, one has to be able to quantify this flow from the streamflow components. This can be accomplished through studies involving different streamflow processes. One such study is the groundwater-surface water interaction study in which the two streamflow components are separated graphically (MacLennan and Bray 1989). Other methods of estimating groundwater discharge involve the use of seepage meters as shown by Lee (1977) and by Lee and Cherry (1978). Difficulties are sometimes encountered when using seepage meters to estimate the groundwater contribution, because certain reaches of the stream are groundwater discharge zones while others are groundwater recharge zones. Zones of groundwater recharge are identified where the water is entering the stream's bed whereas zones of groundwater discharge are identified where the groundwater is exiting the stream's bed (Freeze and Cherry 1979). Groundwater discharge can also be studied using a series of groundwater observation wells. The observation wells are used to develop rating curves relating the levels within the wells to the groundwater discharge during the recession (Rasmussen and Andreasen 1959). The stream is in recession when groundwater discharge is the only streamflow component present. Groundwater discharge is then estimated throughout the year using the rating curve. Another approach for groundwater analysis is the study of the streamflow hydrograph at a gauged station (Linsley et al. 1949). The streamflow hydrograph, which is the sum of all streamflow components, is separated into different components and groundwater (or base flow) is identified.

In this study, a streamflow hydrograph analysis was carried out to differentiate base flow from the total streamflow. The term "base flow" was used in this study rather than "groundwater flow" because base flow includes not only the groundwater discharge but also the water that comes from other storage such as lakes, swamps, and the channel itself.

The objective of the present study is a first step at better understanding the hydrology of the Gulf Region as it pertains to base flow and its potential impact on fisheries resources. To realize this objective, base flow characteristics were estimated for three rivers in the region. These characteristics are: 1) base flow recession parameters, 2) monthly base flow, and 3) ratio of monthly base flow to total flow.

STUDY AREA

The three study rivers are located in the Gulf Region (Figure 1). They are: the Kouchibouguac River in New Brunswick; the Wilmot River in Prince Edward Island; and the Ste. Genevieve River in Newfoundland. These three river systems are part of different geological and hydrological regions. Both the Kouchibougac and Wilmot River are in the Carboniferous-Permian bedrock formation (Macpherson, 1972). This bedrock formation is characterized by sandstone, shale and some coal. The Ste. Genevieve River is situated in the Cambrian-Ordovician-Silurian bedrock formation (Macpherson, 1972) which is characterized by undeformed sediments.

Two of the three study rivers (Kouchibouguac and Ste. Genevieve Rivers) are in close proximity to "index" rivers, selected by the Department of Fisheries and Oceans (DFO), for which fish movement and densities are monitored. This may permit a comparison of the hydrologic characteristics detailed in this report.

The Wilmot River has a drainage area of 45.4 km² while the Kouchibouguac River drains 177 km². The Ste. Genevieve River, which is the largest, has a drainage area of 306 km². The Wilmot and Kouchibouguac Rivers have similar geomorphologic characteristics (Figures 2, 3; Table 1). A significant portion of the Ste. Genevieve River basin comprises of lakes, unlike the other two basins (Figure 4). Other geomorphologic characteristics of the three studied rivers are presented in Table 1.

GROUNDWATER ANALYSIS

Streamflow components

To study the groundwater flow or base flow using the discharge hydrograph, it is important to understand its different streamflow components. As shown in Figure 5, these components are: a) surface runoff or direct runoff, b) channel precipitation, c) interflow, and d) groundwater flow or base flow (Viessman et al. 1977). Surface runoff refers to the flow of water over the land's surface, which occurs during and immediately after rainfall. The rate of surface runoff depends on the surface-type with different surfaces being characterized by different surface runoff coefficients. Channel precipitation is defined as the amount of precipitation that falls directly into the stream; which is concurrent with the precipitation. Interflow is water that infiltrates the ground but does not reach the groundwater table; it occurs during part of the surface runoff period and generally continues to the end of the surface runoff. Interflow, being within the upper layer of soil, travels faster than the deeper types of groundwater. The last component of the discharge hydrograph is the groundwater flow or base flow. Base flow is the water that keeps the river flowing following the end of the surface runoff. Part of the base flow is water that has reached the water table and is reentering the stream through groundwater discharge zones. A portion of the base flow can also originate from basin storage (e.g. lakes and swamps). Because of the absence of the other components, the base flow recession period is often used for groundwater discharge analysis.

Base flow recession analysis

The base flow recession analysis method used in this study consists of studying characteristics of the streamflow hydrographs for different base flows during recession. The hydrograph is in a state of base flow recession immediately following the end of the surface runoff period. At this point the precipitation has also ceased for a period of time (Figure 5). This portion of the hydrograph (base flow recession) has the particular characteristic of following an exponentially decreasing curve. The base flow recession period of the hydrograph as shown by Barnes (1939) and by Hall (1968) follows one of the following exponential equations:

[1]
$$Q_t = Q_0 K_r^t$$
 or $Q_t = Q_0 e^{-a_1 t}$ with $e^{-a_1} = K_r$

$$[2] \qquad Q_t = Q_0 \exp(-a_2 t^n)$$

where Q_t is the discharge at time t and Q_0 is the discharge at time zero (or initial discharge). K_r (the recession constant), a_1 , a_2 , and n are base flow recession parameters. In [1] and [2] e and exp represent the natural logarithm.

Equation [1] yields a straight line when the logarithm of discharge is plotted against time. To obtain a straight line with equation [2], the logarithmic transformation is applied twice on discharge and once on time. These transformed variables can be studied graphically to identify recession periods. Once a series of recession periods are identified, the equation parameters can be estimated and compared for different flows or different river systems. The geometric mean, another calculated parameter, reflects the magnitude of streamflow during the recession. It is preferred over the arithmetic mean when dealing with exponentials. The geometric mean is obtained by the following equation:

$$[3] \qquad X_g = \exp(\sum_{i=1}^{N} \{\ln Q_i\})$$

with N representing the duration of the base flow recession period in days, Q_i the discharge of the i-th day, and In the natural logarithm.

From a fisheries perspective, it is important to understand the base flow recession curve characteristics for at least two reasons: a) they give an indication of the rate of depletion of storage (or groundwater) for the basin, and b) they provide a forecasting tool for drought and low flow analyses. In anticipation of a drought, the base flow recession curve can be used to estimate the degree of low flow. Mitigative measures can be implemented to protect fishes and their habitats in multi abstraction watercourses.

Hydrograph separation techniques

It is important to estimate the base flow throughout the year. This estimate permits a comparison of groundwater contributions from one year to the next or between drainage basins. The base flow hydrograph can be obtained through a separation of the streamflow components. Several techniques have been proposed (Linsley et al. 1949) and many of them are described in Cormier (1986). Some of these techniques can be analyzed analytically but most of them are graphical. It is not the purpose of this report to present all of the possible methods but rather, to appreciate the differences in the outcome of such methods; a few of them are discussed below.

In the application of any hydrograph separation technique, one must first look at the hydrograph and identify the beginning and the end of surface runoff. These two points are identified by A and C (or C') on Figure 6. The beginning of surface runoff is easier to establish than the end because it is often associated with a distinct rise in discharge. One method of identifying the end of surface runoff is to apply the following rule of thumb (Linsley et al. 1958):

$$[4] N = A^{0.2}$$

where, N = duration of runoff in days, and A = drainage area in square miles

Another method of identifying the end of surface runoff is to plot the logarithm of discharge versus time. If the base flow recession curve follows an exponential curve, as described in the previous section, then the transformed hydrographs should yield a straight line following the end of runoff.

Assuming that the beginning and the end of surface runoff can be estimated, the hydrograph separation technique consists of drawing a straight line between the two points (i.e. between points A and C, Figure 6). A second method consists of continuing the base flow of the previous recession until the hydrograph reaches its peak. This is shown as point B (Figure 6). A straight line is then drawn from point B to point C. The third method is the straight, horizontal line separation. This method consists of drawing a straight horizontal line from the beginning of the surface runoff to the intersection on the discharge hydrograph (point C' on Figure 6).

These methods are fairly simple to apply provided that the hydrograph is well defined by a single storm event. Hydrographs resulting from more than one storm or from a combination of snow melt and precipitation are often complex and the separation more difficult. Such complex hydrographs are often observed in northern countries like Canada. Meyboom (1961) and Chernaya (1969) described a method of separation which can be utilized in these situations. This technique consists of studying the hydrograph for a longer period (e.g. annual) rather than on a storm event basis (Meyboom 1961). If the logarithm of discharge is plotted against time, low flows often result in a straight line. This method, also known as the Envelope Method, consists of joining the low flows by straight lines on a log-transformed graph.

RESULTS

Base flow recession curve characteristics

The data used in this study were daily mean river discharges (Environment Canada, Inland Waters Directorate, 1970..1988) and daily precipitation (Environment Canada, Atmospheric and Environment Service, 1970..1988). Base flow recession periods were identifed using streamflow hydrographs and precipitation records. However, precipitation records did not always help identify the base flow recession period because precipitation did not necessarily produce an increase in discharge. This was observed during winter when precipitation is often in the form of snow and also during the summer when infiltration, transpiration and evaporation are high. Base flow recession periods identified for the Ste. Genevieve River in 1978 are shown in Figure 7. Once the recession periods were identified, a log plot of discharge vs time (equation [1]) and a log log plot of discharge vs log of time (equation [2]) of each recession period were studied graphically. The selected base flow recession periods were then fitted to equation [1] and [2] by regression analysis. The results of this analysis are presented for Wilmot River (Table 2), for Kouchibouguac River (Table 3) and for Ste. Genevieve River (Table 4).

Each table contains information on the start, the end and the duration of the base flow recession period. The end of the recession period was identified by an increase in discharge as shown in Figure 7. K, was calculated using the relation in equation [1], while X_{g} was calculated using equation [3] The coefficients a_1 , a_2 , and n, of [1] and [2], are the parameters of the recession equations and Qo the initial discharge. The last two columns of these tables were part of the regression analysis with r,2 representing the explained variance (or fit) of equation [1] and r2² representing the explained variance of equation [2]. These last two variables give an indication of which equation best represents the base flow recession characteristics. The results of the explained variance for equation [1] (r,2) and for equation [2] (r_{2}^{2}) shows no evidence that one equation is better than the other. It was also noted from these tables that Ste. Genevieve River had more identifiable base flow recession periods than the other two rivers.

Monthly and annual base flow characteristics

The identification of the end of surface runoff using the log transformed plot was very difficult to apply because the transition was often gradual. In addition, even when the base flow recession curve fitted the exponential curve well, a straight line was not always evident. Snowmelt and precipitation were also factors contributing to the complexity of some hydrographs, which made it very difficult to identify the end of surface runoff. In view of this, the Envelope hydrograph separation technique was chosen. Straight lines were then drawn joining low flows of the log transformed graph (Figure 8a). This process was carried out systematically each year, for every river system. Once the separation was completed, the equation of each exponential line was determined by identifying the end points. Knowing the parameter of each line, the base flow hydrograph was reconstructed (the hatched area of Figure 8b). Then, using the base flow hydrographs, the monthly base flows were calculated (Tables, 5-7). These tables show that the months with the highest base flow contribution are April-May for Wilmot and Kouchibouguac River, and May-June for Ste. Genevieve River. The variation in annual mean base flow is consistent between drainage basins, with coefficients of variation ranging from 20.9% to 24.2% (Tables, 5-7).

In base flow studies, the ratio of base flow to total flow is used as a variable to show when the groundwater or base flow contribution is the most significant (MacLennan and Bray 1989). This ratio is also used as an index to compare different basins in a studied region. Tables 8-10 present the results of the ratio of base flow to total flow for the three studied rivers. These tables show the importance of base flow during the summer period with ratios in the 0.80 to 0.90 range with relatively low coefficients of variation for Wilmot and Ste. Genevieve Rivers. Kouchibouguac River shows lower ratios of base flow to total flow for these months and values ranging from 0.47 to 0.62 throughout the year (Table 9).

Discussion

This report presents groundwater related data for three Gulf Region rivers obtained by calculating base flow characteristics. These characteristics include base flow recession parameters, monthly base flow, and monthly ratio of base flow to total flow. Further development of the present study could include a study of the base flow recession constant K, as a function of average discharge (X_g) and comparing the results for different river systems. Streamflow characteristics, such as those used by Frenette et al. (1984), could be studied using not only total flows (Frenette et al. 1984) but also base flows in the analysis. This could help to identify which streamflow component best explains size or density of fish populations.

Acknowledgements

The author would like to thank the following people for their contribution in this study: R. Boudreau for his work on this project as a summer student; J. Conlon for his assistance in the preparation of tables and figures and for his comments on the manuscrit. A.T. Bielak , T.W. Hennigar and R.A. Cunjak kindly reviewed the report. Many thanks are also offered for the provision of data by the Data Control Section of Environment Canada, Ottawa.
