## ABSTRACT

Heizer, S.R. 1990. Escapement enumeration of salmon passing through the Stamp Falls Fishway on the Somass River system, 1986 through 1989. Can. Ms. Rep. Fish. Aquat. Sci. 2067:55p.

The salmon spawning escapements passing through the Stamp Falls Fishway were determined for the years 1986 through 1989. The estimates were made by video techniques in 1986 and 1987, by a combination of video and visual techniques in 1988, and by visual techniques alone in 1989. Numbers of chinook escaping increased during the years studied ( $1986-35,121,1987-53,216,1988$ 76,320 and $1989-79,225$ ), while numbers of coho, sockeye and steelhead fluctuated ( coho -- 1986-27,195; 1987 - 17,050; 1988 - 12,329; 1989-41,129; sockeye -- 1986-33,475; 1987 55,160; 1988-24,015; 1989-38,785; steelhead -- 1986-561; 1987-825; 1988-947; 1989-635). Mark incidence and sex composition data were taken for chinook salmon. Chinook sex compositions varied over the study years from 1 male: 1.38 females to 5.37 males:1 female. Mark incidence for chinook varied from 1 mark:77.7 unmarked fish to 1 mark:87.3 unmarked fish.

Key words: Somass, Stamp Falls, chinook, salmon, escapement, video, visual, mark incidence, sex composition

## RÉSUMÉ

Heizer, S.R. 1990. Escapement enumeration of salmon passing through the Stamp Falls Fishway on the Somass River system, 1986 through 1989. Can. Ms. Rep. Fish. Aquat. Sci. 2067:55p.

Les échappées de saumons géniteurs qui traversent la passe migratoire de Stamp Falls ont été établies pour les années 1986 à 1989. Les estimations ont été faites au moyen de technique vidéo en 1986 et 1987, d'une combinaison de techniques vidéo et visuelles en 1988, et seulement par des techniques visuelles en 1989. Le nombre de saumons quinnats de l'échappée a augmenté au cours des années à l'étude (1986-35121, 1987-53 216, 1988 76320 et 1989-79225), tandis que le nombre de saumons cohos, de saumons rouges et de truites arc-en-ciel a varié (saumon coho - 1986-27 195; 1987-17 050; 1988-12 329; 1989-41 129; saumon rouge -1986-33 475; 1987-55 160; 1988-24 015; 1989-38 785; truites arc-en-ciel-1986-561; 1987-825; 1988 - 947; 1989-635). Les données sur l'incidence des poissons marqués et sur la composition selon le sexe ont été enregistrées dan le cas du saumon quinnat. La composition selon le sexe du saumon quinnat a varié au cours des années à l'étude passant de 1 mâle pour 1,38 femelle a 5,37 mâles pour 1 femelle. L'incidence des poissons marqués dans le cas du quinnat est passé de 1 poisson marqué pour 77,7 poissons non marqués a 1 poịsson marqué pour 87,3 poissons non marqués.

Mot clés: Somass, Stamp Falls, quinnat, saumon, echappée, vidéo, visuelle, incidence des poissons marqués, répartition des sexes

## INTRODUCTION

In 1984 Canada and the United States agreed on a management program directed at the rebuilding of chinook salmon (Oncorhynchus tshawytsha) stocks on a coastwide basis for a 12 to 15 year period. In 1985, a treaty was signed between the governments of Canada and the United States covering Pacific salmon. This treaty was to; 1) limit the interception by each country of the other countries salmon, 2) ensure that each country received benefits equivalent to the salmon produced in its waters, and, 3) to maximize the sustainable production of salmon along the west coast of North America. A major requirement of the agreement was to build chinook salmon stocks, which have been in a state of declining abundance, to optimum levels by 1998.

Rebuilding chinook salmon stocks required special enhancement and management actions. In response to this the Department of Fisheries and Oceans (DFO) initiated the Key Streams program in 1984. The program was designed to monitor BC chinook salmon stocks with the following objectives:

1) to evaluate the stock rebuilding program;
2) to accurately estimate the escapement to the key streams;
3) to estimate harvest rates and contributions to fisheries based on an analysis of coded wire tag (CWT) data including estimates of the total escapement of coded wire tags to the system;
4) to estimate the relative contributions of hatchery and wild/natural production to the escapement; and
5) to develop the database necessary to carry out stock/recruit analysis, and compare productivity between stocks.

Key streams were chosen for extensive study based on the following criteria; a) the existence of a hatchery to supply juvenile chinook salmon for coded wire tagging; b) accessibility for field sampling; c) feasibility of fence operations; d) geographic locations with respect to other key streams such that different areas of the coast would be represented in the program; and e) the presence of a relatively large chinook salmon escapement.

The Somass River drainage, specifically the Stamp River, a major tributary of the Somass (Fig. 1) was selected as an key stream in this program. This system supports the largest chinook salmon population on the West Coast of Vancouver Island and meets all of the above criteria although installation of a fence would be costly.

As a consequence of this selection, a study was initiated in 1984 to estimate escapement of chinook salmon to the Somass River
system (Lightly et al., 1988). This study used three indices of abundance: fishway counts, dead pitch of adults, and a Petersen mark/recapture study. The results showed a river escapement in 1984 of 56,000 chinook salmon, an order of magnitude higher than previous estimates (ibid.).

This system was studied again in 1985 and 1986, but results have not been published to date. The 1986 study was done using a video camera installed in the fishway at Stamp Falls but details of the installation and methodology are not available to me.

This report will document the studies I conducted during 1987, 1988 and 1989, and will report on results of a rereading of the video tapes from the 1986 study.
STUDY AREA
The Stamp Falls Fishway is located 14.1 km upstream from tidewater on the Stamp River, which drains Great Central Lake (Fig. 1). Chinook salmon returning to spawn above this fishway are the majority of chinook salmon returning to the Somass system, and only exclude those returning to the Sproat River which at its confluence with the Stamp River ( 6 km downstream from the fishway) forms the Somass River. With the exception of the Sproat River stock, then, chinook salmon passing through the fishway can be considered to be the total escapement to this system.

The fishway is a bottleneck in the system and all chinook salmon must pass through it except at times when water flows allow them to circumvent the fishway by ascending the Falls. For this reason, the fishway was selected as the counting site for the study periods covered in this report.

## METHODS

## 1987

The study period in 1987 ran from September 28 to November 17. The objectives of the study were to determine; (1) the numbers of salmon and steelhead trout (Salmo gairdneri) passing through the Stamp Falls fishway, (2) the sex composition of coho ( 0 . kisutch) and chinook salmon, and (3) the incidence of adipose clipped chinook and coho salmon and steelhead trout. The missing adipose fin flags the presence of a coded-wire-tag (CWT) imbedded in the snout.

Salmon passing through the fishway were enumerated by means of a video camera (Panasonic WV-CD 110)installed in the fishway and aimed at an orifice at the confluence of a pair of leads installed just downstream of the upstream exit of the fishway. The leads were designed to force fish to swim through the area viewed by the camera (Fig. 2). Later, as the video tapes (made on a JVC BR9000U VCR) were read, numbers of fish going up or down the fishway were recorded. Numbers going up minus those going
down (for each category) was the net escapement of that category.
The camera ran 24 hours a day except when the video tape was changed, when the fishway was closed so as to take biological samples or to calibrate the camera (see discussion of these subjects below), during malfunctions, and when water levels were too high to allow access to the installed equipment. A gate was closed across this orifice when the camera was not running.

During the study, 127 video tapes (which recorded 8 hours of "real" time each) were generated. These tapes were viewed using a stop motion VCR identical to the one on which they were originally recorded. The tape readers recorded numbers of each species of fish, their sex, and whether they had a missing adipose fin.

Sex of fish was determined by using external characteristics as indicators. These characteristics were colour, size and shape of head.

Field crews at the fishway also attempted to tag a portion of the run with numbered Petersen disk tags pinned to the dorsal musculature of the fish. If these tags were seen during replay of the video tapes, this would be evidence that some fish went back downstream over the falls, and later reascended the fishway where they would be counted a second time. Any tagged fish going down the fishway rather than over the falls would have been recorded on the video tapes.

Floy tags were also applied at the fishway so that an independent estimate of the escapement could be made as a check on the counting techniques.

As a check on the ability of tape readers to correctly determine species, sex and missing adipose fins, a "calibration" or comparison of actual numbers of fish swimming through the fishway with those determined by reading video tapes was attempted. To this end, a trap was installed in the fishway and was operated at intervals (Fig. 2). Numbers, species and sex of fish caught were recorded and compared with fish observed on video tapes for the same period. As a check on reader bias, 12 tapes were reread by a second reader (See Appendix 2.)

## 1988

In 1988, escapement passing through the fishway was enumerated during the period Sept 15 through Nov 20. The execution of the project was modified considerably for this season due to limitations of the video technique experienced in 1987. Counts of fish by species were done visually by observers counting fish as they passed over a flashboard as they exited the fishway.

Video cameras were again employed in 1988, this time for slightly different purposes. Two taping sessions occurred each day, one with the camera taping from above for 2 hrs , and one from the side for 4 hrs . The overhead view tapes provided images which were measured against reference marks on the flashboard for a sample of chinook salmon lengths, and the side view tapes were
taken to determine sex and presence or absence of adipose clips. Grids were installed to block the fishway and to force fish to swim through two chutes where they were counted as they passed over a flashboard floor in each chute ("A" in Fig. 3). Gates in the grids closed off the chutes for periods when counting was not being done. Later in the season only one chute was employed ("B" in Fig. 3). Technicians were instructed to count between dawn and dusk, the period during which there was adequate light for observations.

A video camera was employed which was mounted directly over a counting chute for the overhead view (Fig. 4), and could be moved to a mount on the side of the fishway for the side view (Fig. 3). Lee et. al. (1989) further document the details of installation and operation of the cameras and other hardware used in this project in an unpublished consultants report available at South Coast Division offices.

## 1989

The project ran from Sept 14 to Nov 19 in 1989, and was again modified from prior years. Results of earlier work indicated that trying to determine sex, age and mark incidence by video or visual means at best provided data of questionable accuracy, and at worst was extremely costly and erroneous. Consequently, for the 1989 enumeration, no attempt to assess sex composition, mark incidence or age composition at the fishway was made. Observers counted the numbers of salmon passing through the fishway in a counting chute identical to that employed in 1988 ("B" in Fig. 3) with a flashboard bottom, and periodically operated a trap (Fig. 5) to validate observers ability to count and speciate fish.

Observers were required to enumerate jacks as category separate from adult fish. Jacks were arbitrarily classified as fish with fork lengths of less than 520 mm . The trap was also to be operated so that scale samples and sex information could be taken from a subsample of chinook salmon of fork length less than 590 mm. These data would allow determination of whether fish in this subsample were true jacks (precocious 2-year-old males) or smaller older fish.

## REREAD OF THE 1986 VIDEO TAPES

Video tapes were made in 1986 yielding results which were questioned regarding accuracy. As a consequence, these tapes were read again, and numbers of chinook salmon were increased at the expense of coho salmon as the second reading revealed that chinook salmon were incorrectly identified as coho salmon. No rationale for this change or documentation of the criteria was available, so it was decided that the tapes should be read a third time by the contractor who had done the 1987 reading and presumably had adequate expertise.

## RESULTS

## 1987

## Escapement

Net escapement estimates (Table 1) constitute the sum of all fish of a particular species (regardless of sex or marks) going up through the fishway minus the sum of all fish of the same species going down through the fishway. The "unknown" category includes all fish which could not be clearly identified as to species. Some pink salmon (O.gorbuscha) chum salmon (o. keta) and "trout" (Salmo spp.) were counted, but were numerically insignificant. Estimated net escapements including jacks were 53,216 chinook salmon, 17,050 coho salmon, 55,160 sockeye salmon, 825 steelhead trout and 2,364 unknown salmonids (Table 1).

## Mark ratio

The ratio of marked (adipose clipped) to unmarked salmon passing through the fishway is shown for chinook and coho salmon and steelhead trout in Table 2. Mark ratios by sex for chinook salmon are shown in Table 3.

In 1987, tape reading was proceeding so slowly that the readers were instructed not to check for adipose marks (except for chinook salmon) partway into the run. As a consequence, mark ratios for coho salmon and steelhead trout are for the early part of the run only. The "unknown marks" category for chinook salmon includes those fish which could not be assigned presence or absence of an adipose fin but the "unknown marks" category for coho salmon and steelhead trout includes fish with presence or absence of adipose fin undetermined and all fish from the latter part of the run. Marked to unmarked ratios were 1:77.7 for chinook ( $1.3 \%$ marked), 1:35.6 for coho (2.7\% marked) and 2.03:1 for steelhead ( $67.0 \%$ marked).

## Sex

The sex ratio for chinook and coho salmon and steelhead trout is shown in Table 4. An "unknown" category for chinook salmon includes those fish for which sex could not be ascribed. For coho salmon and steelhead trout, "unknown" includes, as well, all fish later in the run as the readers were instructed not to check for sex of these species in the interest of getting the tapes read quickly. As for marks, then, sex ratios for coho salmon and steelhead trout are for the early part of the run only. The ratios of males (not including jacks) to females were 5.37:1 for chinook ( $84.3 \%$ males), $1.25: 1$ for coho (55.6\% males) and 0.85:1 for steelhead (45.9\% males).

## Timing

Fig. 6 shows the timing of chinook salmon males, females and jacks passing through the Stamp Falls Fishway for 1986-1989. Fig. 7 shows the timing of coho salmon, Fig. 8 shows the timing of steelhead trout and Fig. 9 shows the timing of sockeye salmon for 1986-1989.

## Tags

A total of 70 Petersen disc tags and 58 Floy tags were applied by observers. Tagging was not successful as water temperatures were high and chinook salmon were badly stressed during tagging operations. Concerns about mortality induced by tagging led to the cancellation of this aspect of the study: Of the tags applied, 16 Petersen tags and 13 Floy tags were recovered at the Robertson Creek hatchery. None were seen in the video tapes. No attempt was made to search for tags in the river.

## Discussion

Other species - The numbers of sockeye salmon passing through the fishway was surprising. Sockeye salmon returning to the Somass system are counted using Pulsar conductivity counters (Pulsar Electronics, 533 Bournemouth Cr., N. Vancouver, BC V7H 2G4), one in the fishway on the Sproat River and one in the fishway at the dam at the exit of Great Central Lake (Fig. 1). These counters are removed before the chinook salmon migration as the counting tunnels are too small for chinook salmon to pass through.

Sockeye salmon returns to the Somass system were estimated to be 298,322 in 1986; 376,870 in 1987; 430,196 in 1988 and 403,453 in 1989 (Dr. Kim Hyatt, pers. comm.). Sockeye salmon counted during the Stamp Falls project are not included in these estimates, yet constitute significant percentages of the total return (11.2\%-1986, 14.6\% - 1987, 5.6\%-1988 and 9.6\% - 1989).

Error - There are errors associated with counting, with sex determination, and with species determination. Appendix 2 contains a discussion and analysis of error in this study.

The calibration attempts indicate that the video method of counting chinook salmon provides estimates with an error of approximately +/- 10\%. Rereading the tapes a second time suggests that there is no significant reader bias, but the rereading design was faulty and did not allow a fish by fish comparison; hence, species identification biases were not able to be assessed. The total count (all tapes summed) is remarkably similar ( $1 \%$ difference) but the absolute relative difference, comparing tape to tape, was much larger (16.5\% for chinook salmon): Errors appear to have cancelled.

Results of the error analysis conclude that the videotaping technique provides reasonable counts of chinook salmon through the fishway. The analysis further concludes that the technique is not recommended for assessment of sex ratios or marked to

Sex
The subsample of side view tapes, used for determining mark incidence, was also viewed for sex composition. Table 4 presents these results. Sex ratios (M:F) were 1:1.38 for chinook salmon (42.0\% males) and 1:1.68 for coho salmon (37.3\% males).

## Length

A random subsample of the top view video tapes (13 of the 34 tapes made were read due to time and financial limitations) was examined and a length-frequency histogram plotted (Fig 10). This plot implies age composition: The first peak is likely 3-year olds, the second a mixture of 4- and 5-year olds.

## Timing

Figs. 6, 7, 8 and 9 show timing of, respectively, chinook salmon, coho salmon, steelhead trout and sockeye salmon through the Stamp Falls Fishway during the 1988 study.

## Discussion

Error - Attempts to quantify and control error and bias in estimates of escapement, sex ratios and age compositions included:

1. comparisons between readers reading the same tapes;
2. comparisons between field counts and tape counts including effects on total counts, species and sex identification;
3. identification and quantification of bias in
determinations of sex and length.
These elements are dealt with in some detail in Lee et al. (1989). The between reader comparisons show that, as in 1987, the total counts are quite similar (mean for the test tape was 418 salmon, with a standard deviation of 8.98 and covariance of 2.15) but that species counts, and more particularly sex determination counts vary considerably. In all probability, sex composition data should be ignored from 1987 and 1988 as it appears that the video taping method is not a reliable technique for sex determination. It is, however, included here in the interest of completeness.

Length measurements suffered from three sources; (1) the accuracy and precision of the measurements inherent in set-up in the fishway, (2) bias introduced through parallax (due to the fish being closer to the camera than the reference lines on the flashboard), and (3) bias due to the exclusion of large fish from the length samples. The exclusion of large fish occurred as some chinook salmon (those larger than 950 mm .) did not always fit entirely in the viewing window in a single frame of the tape, and the computer software employed to measure and record the lengths was unable to accommodate by taking lengths from multiple tape frames.

Accuracy was tested by replicate measurements of a known point-to-point distance and was determined to be $+/-7 \mathrm{~mm}$ in 500 mm (that is, 1.4\%). This was done for replicates of the 500 mm index mark on the flashboard from the same video frame, and also for similar measurements of the index lines from different frames. The mean was within 1 mm of the true value, and had $95 \%$ confidence limits of less than 5 mm .

Mean bias due to parallax was calculated to be $+3 \%$ for length measurements thus a correction factor of .97 x biased length should be employed for lengths taken in 1988.

Bias due to exclusion of larger fish was calculated by using measuring software which was able to take lengths from multiple frames. This development came too late to be used for the whole of the 1988 season. Table 5 shows calculated proportional multipliers by size class which should be applied to the initial biased sample sizes. Length data in Fig 10 and the text discussion have not been corrected for this bias.

## 1989

## Escapement

Table 1 shows the net escapement past the Stamp Falls fishway in 1989. Linear interpolations were made for periods during which no counts could be made. A total estimated net
escapement for chinook salmon should also include 3,141 chinook salmon mortalities found in the area below Stamp Falls and sampled by staff from the Robertson Creek hatchery. This total is 82,366 including jacks, or 79,225 live chinook salmon through the fishway plus 3,141 mortalities. There were, as well, 41,129 coho salmon (including jacks), 38,785 sockeye salmon, 635 steelhead trout and 1398 unknown salmonids.

## Sex

Table 6 documents sex information taken at the time the mortalities below Stamp Falls were examined.

## other sex information

During the season, Robertson Creek hatchery staff noticed a disproportionate male to female ratio in the escapement of chinook salmon to the hatchery (7:1). Consequently, fishway observers recorded their assessment of numbers by sex on 24 days between Oct 20 and Nov 19. Of the 5,313 chinooks counted during this period, 1,734 (32.6\%) were females (see App. 1, Table 8.) The final sex ratio for chinook in the brailer at Robertson Creek Hatchery was $4.66: 1$ or $82.3 \%$ males (Paul Starr, pers. comm.)

## Mark ratios

Mark ratios were not determined for the 1989 study.

## Timing

Figs. 6, 7, 8 and 9 show, respectively, timing of chinook and coho salmon, steelhead trout and sockeye salmon through the Stamp Falls Fishway during the 1989 study. Linear interpolations were made for periods during which no counts could be made. These periods were: 1) October 23-28 due to high water conditions, and 2) November 14 and 15 when a prototype video counter was tested. This correction was done only for the 1989 data.

## Discussion

Attempts were made to quantify errors associated with counting and speciation, but the trapping apparatus designed for this aspect of the study could not be effectively operated without significant modification to both the trap and the fishway.

In spite of this, seven calibration trappings were conducted. Two of these attempts were invalid as the area between the trap and the chute was not tight and some fish were able to escape. Four calibrations indicated no error, and during one calibration, the observer incorrectly identified a coho as a chinook jack. In 5 of the seven calibrations, no counting error occurred. These data are not conclusive, but do indicate that
observer accuracy can be high under good viewing conditions.
Only one sample of small chinook salmon was trapped to determine observer accuracy in correctly identifying chinook salmon jacks. The sample size was too small and did not cover the appropriate size range. Information from Robertson Creek hatchery reported to the contractor (Wright, 1990) indicates that less than $1 \%$ of chinook salmon sampled in the $52.1-59.0 \mathrm{~cm}$ range are jacks, and that all chinook salmon with fork lengths of less than 52.0 cm are jacks.

## 1986 REREAD

## Escapement

Estimated net escapement of chinook, coho and sockeye salmon and steelhead trout passing through the Stamp Falls Fishway in 1986 are shown in Table 1. Estimated net escapement was 35,121 chinook salmon, 27,195 coho salmon, 33,475 sockeye salmon, 561 steelhead trout and 14,862 unknown salmonids. The large number of unknown salmonids was due to very poor video images on the 1986 tapes.

## Mark ratio

Only chinooks were examined for marks. The marked:unmarked ratio for all chinook salmon was $1: 79.6$ or $1.2 \%$ marked (Table 2.) Table 3 shows the mark ratio by sex.

Sex
Chinook salmon were also examined for sex. The sex ratio (males:females) was 1.06:1 (51.5\% males), not counting jacks (Table 4).

## Timing

Figs. 6, 7, 8 and 9 show, respectively, timing of chinook salmon, coho salmon steelhead trout and sockeye salmon through the stamp Falls fishway during the 1986 study.

## DISCUSSION OF 1986 THROUGH 1989 RESULTS

Fishway count estimates of escapement are subject to error as discussed in the sections above dealing with each years design and results.

There are, as well, several additional sources of error which contribute to an underestimate of abundance for each species:

1. An unknown number of fish undoubtedly bypass the fishway completely under certain water flow conditions. It is virtually impossible to assess the degree to which this occurs, but there
are field observations which indicate that under certain conditions, this may be a significant source of error. During the 1989 season, observers noticed large numbers of chinook salmon in the pool below the falls. After the flood of Oct 2326 , during which time hydraulic conditions were suitable for bypass, observers noted a dramatic decline in numbers of chinook salmon in this area.

Observers have witnessed chinook salmon successfully negotiating the falls, and it is likely that the fish seen in the pool below the falls went upstream over the falls during the flood. For the 1989 season, this could have amounted to thousands of chinook salmon.
2. Migration of fish through the fishway both before and after installation of the counting apparatus will also contribute to an underestimate of abundance.
3. There are periods when fish are passing through the fishway and no counts can be obtained. The counting chute required periodic adjustment due to fluctuating water levels, and during these brief periods, fish are able to move through the counting station unenumerated. A combination of turbid water and high flows during the video counting studies allowed fish to pass through the fishway when water was so turbid no filming was possible and flows made it impossible to shut the gate in the grates. This was usually dealt with by extrapolating over the period in question, but this remedy was not appropriate for those situations where the beginning time of a malfunction was unknown.

Errors associated with items 2. and 3. above are likely not large. Migration prior to startup might be controlled by starting the project on September 1 and assessing the extent of the problem. Unknown leaks of fish past the hardware in the fishway might be controlled by modification of the equipment installed. Both of these remedies will be expensive.

The problem of fishway bypass, however, is likely both significant and next to impossible to quantify or remedy. one person involved with the project suggests that some sort of electronic barrier fence installed at the base of the falls might be an effective way of insuring that all fish would be diverted through the fishway.

## RECOMMENDATIONS

If similar escapement estimation studies are to continue on the Somass River system, I believe that several modifications at Stamp Falls will be required:

1. Because of the bypass problem, some sort of barrier should be designed which would force all salmon to pass through the fishway. This could take the form of the electronic barrier fence mentioned above. Stamp Falls is a popular site for tourists and such a provision could be dangerous to the
inquisitive. Moreover, there is no electric power to the site at present and such a provision would be costly.
2. Some method of keeping fish from passing through the fishway during floods (when they cannot be seen) should be developed. This might be achieved by shutting the downstream entrance to the fishway during these periods. This option may increase fish mortalities, however.
3. If video means are employed to count fish, some way must be devised to restrict fish passage past the camera to a rate which yields little or no overlap of fish passing through the viewing area of the camera. As well, the fish will have to be forced to present themselves in a proper orientation to the camera so as to optimize image quality. An appropriately designed chute should remedy this. Adequate artificial lighting will have to be installed. All hardware installed in the fishway will have to be redesigned and constructed so that it is suitably substantial and can be easily accessed and moved during a variety of hydraulic conditions.
4. Due to the high cost of reading video tapes, computer software with the capabilities of discriminating between sexes, and which can determine lengths and presence/ absence of fin clips directly from video tapes could be developed. The costs of this would, however, likely be prohibitively high.
5. It is possible that with encouragement, the prototype video fish counter being developed by RETECH, (Retech, 627 John St., Victoria BC - Michael Roch) and tested at Stamp Falls in 1989, may remedy (3) and (4), but likely will be expensive.
6. If observers are to visually count fish passing through the fishway, then proper chutes which can be raised and lowered for different water levels and which remain "fish tight" will be required. As well, a trap which can operate easily under a variety of hydraulic conditions will be required to do calibrations and validations so as to assess errors and provide live fish for sampling as required. These traps might be designed along the lines of that used in the fishway at Great Central Lake.
7. It is not possible to determine whether the video method is in any way superior to the field observation method since there is no way to determine actual numbers of fish passing through the fishway. In my judgement, the simpler and less expensive method of field counting salmon is the most reasonable method.

I would like to thank Jim Mitchell, Senior Management Technician, and the staff of Robertson Creek Hatchery for their generous and excellent assistance in the execution of this project. As well, I appreciate the reviewers of this document (Rick Semple, Mike Wright and Paul Starr) for their useful and insightful comments.

## APPENDIX 2

## A DISCUSSION OF ERROR IN THE 1987 STUDY

## BY

MICHAEL STALEY 7721 CARTIER STREET VANCOUVER, BC V6P 4T2

Work done for DFO under Contract (Contract Number V5843336)

## INTRODUCTION

Three data sources were analyzed for error from the 1987 video experiment. The first set includes the original readings from the complete video tape record. These data were compared with a second set obtained from the operation of a fish trap. The times of the trap opening and closing were matched with corresponding times on the original tape readings and the number, species and sex were compared between data sets. The third data set represents a second reading of selected video tapes. These data were used to assess reader error and bias.

This section of the report first describes the data records and fields. It then presents analysis of the comparison between the video tape data and the fish trap data. The data from the reread tapes is then compared to the data from the original reading. Finally difference between the various readers is calculated and assessed.

## Data description

Each fish observed on the video tapes generated a unique data record. Each record contained the following fields: Date - The date the tape was recorded. Time - The approximate time that fish passed the camera. Tape - The number of the video tape. Species - A species code for each fish. The following codes were used:
CM - chum salmon
CN - chinook salmon
CO - coho salmon
PK - pink salmon
ST - steelhead trout
SX - sockeye salmon
T - other Trout
UCM - unknown but probably chum salmon
UCN - unknown but probably chinook salmon
UCO - unknown but probably coho salmon
UPK - unknown but probably pink salmon
UST - unknown but probably steelhead trout
USX - unknown but probably sockeye salmon
UT - unknown but probably trout
U - species unknown

- A code for each sex as follows:
F - female
$M$ - male
$J$ - jack
$U F$ - unknown sex probably female
UM - unknown sex probably male
UJ - unknown sex probably jack
$U$ - sex unknown

Mark - To indicate if the adipose fin was present or missing. The following codes were used:
Y - Adipose fin was present
N - Adipose fin was missing U - Unable to determine presence or absence of adipose fin.
UpDn - A U (up) or a D (down) were used to designate
Reader - the direction of travel.

- The initials of the person that read the tape.
Page - The page number of the data entry sheets.

The data taken from the trap counts had the following fields: Date, time, species, sex, mark. Usually the species and sex were known, however, sometime fish escaped the trap without identification and sometimes without being counted.

## Data preparation

The data were keypunched and "cleaned". Cleaning was done by resolving invalid field codes and by various crosstabulations for obvious conflicting fields, such as date and tape number. The data base was searched for invalid codes or data and each nonconforming record was reviewed and corrected. This procedure does not ensure total accuracy of the data entry process. However, given the nature of the data, this procedure was adequate.

The data from the video tape readings were corrected for up-and-down stream movement of the fish. The number of records with a $U$ in the UpDn field were reduced by a corresponding number of records with $D$ in the UpDn field. This procedure assumed that each fish seen travelling down stream had previously been counted going up stream.

Appendix 2, Table 1 presents the total counts by species read from the video tapes and transcribed by the video tape readers. The number up, down and corrected are shown. In addition the relative number of unknown and unknown but probable species are also shown.

## Calibrations with Trap Data

Calibration events were defined as comparison of counts from the video tapes with counts from a trap in the fishway. These counts were conducted at the same time. The purpose of this procedure was to test the accuracy of the video tape data by comparing selected video counts with direct visual counts in the trap. Data from the trap were matched with the original video tape data by extracting the video tape counts for the corresponding date and time. Appendix 2, Table 2 presents the list of calibration events.

Except for calibration event numbers 36,43 and 44 there were records of fish passage from the video tape for all events. The corresponding dates and times for these missing events were not in the data base. Further investigation of the data indicated that the tapes were either blank or black during these episodes. Therefore, these data were left out of the analysis.

Appendix 2, Table 3 through Appendix 2, Table 5 present the comparisons of fish counts from the video tapes and the traps for chinook, coho and sockeye salmon respectively. Only one steelhead was collected in the trap and it was also seen on the video tapes. No other species were present in the trap or identified on the tapes during a calibration event.

For the counts of chinook, coho and sockeye salmon a calibration factor between the video tape readings and the trap counts was calculated (Appendix 2, Table 6.) A proportional difference between the count of the species in the trap and the data from the video tapes was calculated for each calibration event. These proportional differences were treated as sample observations of the calibration factor.

Many of the events had a zero count for one of the species. However, there were fish present in all calibration events. Therefore, all 43 calibration events were used as samples in the calculations of the mean and variance of the differences.

The proportional or ratio differences were assumed to be sampled from a student-t distribution. Confidence intervals (95\%) were also calculated using this distribution and are presented in Appendix 2, Table 6 in addition to maximum and minimum population estimates.

Ca'libration factors were also calculated for the sex ratios of chinook salmon. Sex identification for chinook salmon was very poor (Appendix 2, Table 3), however, a calibration factor could be calculated (Appendix 2, Table 6). No sex identification was possible or reliable for coho or sockeye salmon.

For this analysis the proportion of each sex (males, females and jacks) and the variance in the proportions was calculated independently. A sample of ratio differences in the sex proportions was calculated between the tape and the trap data for each sex. A mean calibration and 95\% confidence intervals was also calculated for each sex proportion. The size of the 95\% confidence intervals
(Appendix 2, Table 6) support the conclusion that sex identification with the video tape method is very unreliable.

## Treatment of Unknowns

In this analysis the unknown but probable species records (species codes UCN, UCO and USX) were treated as known species. The remaining unknown species in the calibrations events were then compared with the trap data. Appendix 2, Table 7 presents events where there were unknown species from the readings of the video tapes. As there were only 5 such events and a large variability in the species mix in the trap data no reliable method for allocating unknown species could be developed. However, the occurrence of unknown species in the total data set represents less than $2 \%$ of the total number of fish counted. In light of the size of the calibration factor and confidence intervals presented in Appendix 2, Table 6 these unknown fish are insignificant in relation to the noise or error in the estimates of total escapements.

## Tape Rereads

In addition to calibrating the video data with trap data an attempt was made to measure the degree of error in the process of reading the tapes. Twenty-six of the tapes, representing approximately $20 \%$ of the fish, were reread by different readers. A comparison of the two readings and an assessment of reader bias were analyzed (Appendix 2, Tables 8 and 9).

Unfortunately, the method of recording the times for the fish passage differed between the two readings. This fact made it impossible to match the times recorded for the passage of an individual fish from one reading with the times for the same fish from the other reading. A fish by fish comparison of the two data sets was not possible, instead a tape by tape analysis was done.

Appendix 2, Table 8 presents the counts of chinook, coho and sockeye from the two readings of the tapes. As with the calibration analysis with the trap data, the unknown but probable species were included as known species.

The tape by tape comparisons resulted in large differences in fish counts. The total count from both readings for chinook salmon were remarkably similar (1\% difference). However, the mean of the absolute relative tape to tape difference was much larger (chinook salmon 16.5\%, coho salmon $38.6 \%$ and sockeye salmon $8.5 \%$ ).

Appendix 2, Table 9 presents the average proportional differences (summing pluses and minuses) between the two readings and the $95 \%$ intervals of the sampled distribution. These differences were constructed by treating the counts from each tape as a single sample, providing 26 samples of proportionate differences.

Given the results of the calibrations analyses (with the trap data) regarding sex identification and the difficulty in comparing the two readings no analysis or comparison of sex ratios was attempted.

## Reader Bias

The original readings together with the reread tapes provided an opportunity to assess reader bias. One test of bias involved comparing total counts of fish from the two readings of the tapes. Appendix 2, Table 10 presents the counts by readers (who read 3 or more tapes) and their differences from all other readers that read the same tapes. There were some consistent differences amongst readers but none of the difference were significantly different from zero (to the . 05 level). Given the lack of statistical difference in the total count and the degree of error in species and sex identification present in the calibrations no attempt was made to identify bias in the species or sex identifications.

## Recommendations

The method of counting fish with a video camera shows some promise at providing a reasonable estimate of the total number of fish. The counts of chinook salmon from the video tapes corresponded reasonably well with the calibration events from the trap data. However, the inconsistency between the two readings of the same tapes is disquieting.

From the results of these analyses one can conclude that the video system provides total chinook salmon escapements estimates with an error of approximately $+/-10 \%$ (Appendix 2 , Table 6). Using this method to assess other characteristics such as sex ratios or marked to unmarked ratios cannot be recommended.

The counts of coho and sockeye salmon were much less accurate. This may be because the smaller fish escaped the trap without being counted. If they did escape the trap then the video camera may provide a better method for these species. However, the data analyzed here does not provide enough clarification of the accuracy of the video tape verses the trap.

There does not seem to be a significant reader bias. However if the data from the tapes had been transcribed with times that were consistent from reading to reading, enabled a fish by fish comparison, then certain biases about species identification could have been assessed.

Appendix 2, Table 1. Total counts of fish by species up, down and corrected from original tape readings.

| Species | Movement |  | Corrected | Including unknown but probable |

[^0]:    a Data from which this Table was derived are shown in Appendix 1, Tables 5, 6 and 7.
    b Mark ratios for coho salmon and steelhead trout are from the early part of the run (see p. 5 for explanation).

[^1]:    a Data from which this table was derived are shown in Appendix 1, Table 8.

[^2]:    The numbers in parentheses are percentages of the total deadpitch
