¹ This series documents the scientific basis for the evaluation of fisheries resources in Canada. As such, it addresses the issues of the day in the time frames required and the documents it contains are not intended as definitive statements on the subjects addressed but rather as progress reports on ongoing investigations.

Research documents are produced in the official language in which they are provided to the Secretariat.

¹ La présente série documente les bases scientifiques des évaluations des ressources halieutiques du Canada. Elle traite des problèmes courants selon les échéanciers dictés. Les documents qu'elle contient ne doivent pas être considérés comme des énoncés définitifs sur les sujets traités, mais plutôt comme des rapports d'étape sur les études en cours.

Les documents de recherche sont publiés dans la langue officielle utilisée dans le manuscrit envoyé au secrétariat.

ISSN 1480-4883 Ottawa, 1999

Abstract

A hydroacoustic survey was conducted aboard the *F.G. Creed* in the fall of 1997 as part of a fishery-independent abundance index for the west coast of Newfoundland herring stocks. Systematic-parallel transects were chosen along the coast and were surveyed during night-time hours. Biological sampling was accomplished in collaboration with the western Newfoundland large purse seine fleet, which also took temperature, salinity and depth (STD) profiles. Raw volume backscatter data (Sv) were collected from a 38 kHz transducer, as well as split-beam phase data. This survey revealed that herring concentrations were more schooled than in 1995, closer to shore, more in the upper layers, and displaced towards the north and the south where warmer waters were available at all depths. The vast majority of herring echoes (80%) were recorded north of New Ferrole (stratum 10) and along the coast towards the Strait of Belle Isle. The total combined spring and autumn stock size in 1997 (88,000 t) was relatively stable compared to the 1995 estimate (89,500 t), although the spring-spawning stock decreased by 37% and the autumn-spawning stock increased by 20% over the past two years.

Résumé

Un relevé hydroacoustique fut mené à bord du *F. G. Creed* à l'automne 1997, afin de produire un indice d'abondance indépendant de la pêcherie, pour les stocks de hareng de la côte Ouest de Terre-Neuve. Des transects parallèles ont été choisis de façon systématique le long de la côte et furent sondés durant la nuit. L'échantillonnage biologique fut accompli en collaboration avec la flotte des grands senneurs de l'Ouest de Terre-Neuve, qui a aussi enregistré des profils de température, salinité et profondeur (STD). Des données brutes de réverbération de volume (Sv) à partir d'un transducteur 38 kHz ainsi que des données de faisceaux scindés (split-beam) ont été collectées. Le relevé a démontré que les concentrations de hareng étaient plus regroupées en bancs qu'en 1995, plus près de la côte et dans les couches de surface, et distribuées vers le nord et le sud où les eaux plus chaudes étaient disponibles à toutes les profondeurs. La majorité des échos de hareng (80%) a été enregistrée au mord de New Ferolle (strate 10) et le long de la côte vers le détroit de Belle-Isle. La biomasse combinée printemps et automne de 1997 (88,000 t) est demeurée relativement stable comparée à l'estimation de 1995 (89,500 t), quoique le stock de frayeurs de printemps ait diminué de 37% et que le stock de frayeurs d'automne ait augmenté de 20 % lors des deux dernières années.

Introduction

Since 1989, the Laurentian Region of Fisheries and Oceans has conducted six hydroacoustic surveys of the herring along the west coast of Newfoundland (NAFO division 4R). The objective of this series of surveys is to develop a fishery-independent index of stock abundance for these herring stocks. This document summarises the results from the 1997 survey and compares the results with the time series since 1991.

The hydroacoustic work for this latest survey was conducted aboard the CSS *Frederick G*. *Creed* from October 15 to October 31. In addition, several vessels from the west coast large purse seine fleet were directly implicated in the collection of oceanographic and biological data.

Material and Methods

Study Area and Design

The survey was intended to cover the entire west coast of Newfoundland (Figure 1) from Cape Anguille to the southern end of the Strait of Belle Isle within the 20 to 60 m isobaths (7200 km²). The survey area was stratified based on the major physical features (large bays) and on data on herring distribution obtained from the commercial fishery and past surveys (McQuinn and Lefebvre, 1995a). Historical fishing patterns suggest that in the late fall/early winter, the herring move to the nearshore to concentrate in large, relatively stationary schools in and around several of these bays (McQuinn and Lefebvre, 1995b). In 1997, the strata outer limits were adjusted relative to 1995 to generally correspond to the abrupt depth change (approximately the 60 m bottom depth contour) beyond which few herring have been observed in the past.

The orientation of the transects within each stratum was determined by drawing a baseline parallel to the coastline and selecting transects perpendicular to the line. Systematic-parallel transects were then chosen by dividing the baseline into 200 m wide units, and selecting equidistant lines among the units (Figure 2). Sampling density was designed to be more intensive in strata 1 and 2 (St. Georges Bay) because of the controversy over the biomass estimate of this spawning component (McQuinn and Lefebvre, 1995b). The total number of transects was determined by the available ship time minus 30% for down-time (poor weather, equipment failure, etc.). The transects were run during night-time hours only (17:00-07:00) to avoid day-night differences in fish availability (fish on bottom) and horizontal orientation (tilt angle). Past experience has shown that at this time of the year herring are more likely to rise off the bottom at night and to form into more or less concentrated schools, thus reducing their distribution near the sea floor where they are less distinguishable from the bottom echo, i.e. to avoid dead zone problems (Mitson, 1983).

Biological sampling was accomplished in collaboration with the western Newfoundland large purse seine fleet. A scientific staff was invited aboard each of four purse seiners over the two week period of the survey to take temperature, salinity and depth (STD) profiles and to collect biological samples while the staff aboard the *F.G. Creed* collected the acoustic data. The STD and sampling equipment was installed aboard each fishing vessel for a three- to four-day period. During this time, the seiner remained in close proximity (20-40 km) to the acoustic vessel and conducted regular STD profiles. When significant quantities of fish were detected by the acoustic vessel, the seiner proceeded to the position of the school to make a set for species and size composition determinations. At times, the research purse seiner was unable to make a successful set on detected fish schools.

However, in such cases, biological samples were usually obtained from other purse seiners, including vessels from the small purse seine fleet (< 20 m), which were fishing in close proximity.

Equipment

The echosounder used was the Simrad EK500 which powered a 38 kHz hull-mounted, split-beam transducer. Raw volume backscatter data (Sv) from both transducer frequencies, as well as split-beam phase data were stored on a Pentium PC in real-time using the CH1 software (Simard *et al.* 1998) developed at the Maurice Lamontagne Institute (MLI) and translated into the Femto HDPS format for analysis. The equipment was calibrated before the survey (Table 1) using a target of known reflectivity (-33.7 dB for a 60-mm copper sphere) and following the procedures specified by Simrad (Simrad EK500 Instruction Manual). The beam pattern was also calibrated by scanning the copper sphere throughout the beam using a computer-controlled motorised positioning system (Winch) developed at MLI and by collecting and analysing the data using the Lobe beam-pattern software (Simrad EK500 Instruction Manual).

Data Analyses

Recorded echoes were edited using the Femto HDPS software to eliminate backscatter other than from herring schools (e.g. surface noise, bottom signal, other species, etc.). The species composition of some schools was unconfirmed by biological sampling because we were unable to catch them with the purse seine or there was no fishing activity in the area. In these cases, gross form and density were considered to judge whether or not they were to be included in the analyses. Most fish schools recorded were considered to be herring as very few other fish species with swimbladders were in the survey area at that time of year. Herring schools in the late fall show a relatively limited range of characteristic forms, from candle shaped, to dense domes on the bottom, to large pelagic aggregations 10's of meters thick.

Estimates of area backscatter, stock biomass and variance were calculated following the procedures and equations recommended by the CAFSAC pelagic subcommittee (O'Boyle and Atkinson 1989). Although the application of classical statistics for a random-stratified design to a systematic-stratified survey (1995 and 1997) may lead to a bias in the strata variance estimates, the variance should theoretically be overestimated (Cochran, 1977). We therefore consider the variance estimates presented in the results section to be conservative.

The conversion of backscatter to biomass was accomplished by using target strength estimates per unit length determined from the equation suggested by Foote (1987) for clupeoids at 38 kHz:

$$TS_{cm} = 20 \log L - 71.9$$
 (1)

and for herring at 120 kHz (Foote et al., 1993):

$$TS_{cm} = 20 \log L - 73.5$$
 (2)

where L is the mean total fish length (cm), and by converting to target strength per unit weight:

$$TS_{kg} = TS_{cm} + 10 \log W^{-1}$$

where W is the mean fish weight (kg) (Buerkle, U., pers. com.). The mean lengths and weights were calculated for each transect from the samples most closely associated with each school. Total biomass of spring and autumn spawners was calculated using an estimate of the percent weight of each spawning stock corresponding to each sample.

Equations 1 and 2 are general algorithms applicable for all clupeoids but does not consider the effects of several factors such as fish behaviour (e.g. tilt angle), physiology and depth on the parameters (Ona 1990). As such, the TS values estimated from these equations should be considered as approximate. Although certain measures were taken to reduce interannual variability in TS (surveying at night only; conducting the survey at the same time of year), there may still be inherent biases from the general formula due to the local conditions in 4R which affect the aforementioned factors.

Results

Distribution

In 1997, all the planned strata were sampled acoustically with the exception of stratum 4 and 7 (Port-au-Port Bay and Bay of Islands) where historically few herring have been detected. This survey revealed that herring concentrations were more schooled than in 1995, close to shore, and more in the upper layers (Figure 2). There was also a displacement towards the north and the south with respect to 1995 (McQuinn and Lefebvre, 1996), where warmer waters were available at all depths. Significant concentrations of herring schools were seen in St. George's Bay (stratum 1), and a few schools were recorded off Bay of Islands (stratum 5). However, the vast majority of herring echoes (80%) were recorded north of New Ferrole (stratum 10) and along the coast towards the Strait of Belle Isle (Table 2).

Age Composition

From the numbers-at-age data, the 1987 spring-spawning and 1986 autumn-spawning year-classes, which have dominated these stocks over the past decade, have slowly been replaced by the 1990 year-class, both spring and autumn spawning (Table 3). In 1997, the spring-spawning stock was dominated by the 1990 and 1994 year-classes, while the autumn-spawning stock was dominated by 1988, 1990 and 1993 year-classes, although there was still a large proportion of 11+ fish in the catch.

Abundance Estimates

The 1997 combined total stock biomass was estimated to be 88,000 t, comprised of 24,000 t of spring spawners and 64,000 t of autumn spawners (Table 4). The total stock size was therefore relatively stable compared to the 1995 estimate (89,500 t), although the spring-spawning stock decreased by 37% and the autumn-spawning stock increased by 20% over the past two years. In 1995, 64% of the herring biomass surveyed was in the two most northerly strata, while in 1997, 80% was in the most northerly stratum. Due to the poor performance of the transducer and the incertitude as to the proper calibration parameters (McQuinn and Lefebvre, 1995a), the data from the 1989 survey are not presented here. The biomass estimates for the 1991 and 1993 surveys have been updated from previous

estimates (McQuinn and Lefebvre, 1995b) following a revision of the length/TS equation (2) used for the conversion from echo energy to biomass at 120 kHz (Foote *et al.*, 1993). These revised estimates show a constant decline in the spring-spawner biomass from 1991 to 1997, while the autumn spawners declined from 1991 to 1993, remained stable until 1995 and began to increase in 1997 (Table 4; Figure 3).

The estimates of spawning-stock biomass (mature herring only) of 65,500 t (18,000 t of spring spawners and 47,500 t of autumn spawners) was a decrease over the 1995 estimate of 85,000 t (37,000 t of spring spawners and 48,000 t of autumn spawners). The last 4 surveys have shown a constant decline in the spring-spawners spawning stock-biomass, while the autumn spawners appeared to be stable over the same time period (Figure 4).

Discussion

Abundance Estimates

The 1997 acoustic survey was the most comprehensive survey of west coast herring conducted to date. Biological sampling was improved over past years, although it was noted that the purse seines were limited by adverse fishing conditions (e.g. high winds, fish on bottom, fish not schooled, etc.) and could not always fish on significant concentrations of herring. In addition, large areas of thinly distributed herring were not sampled, and although this did not represent a large percentage of the total area backscatter, confirmation of species and length composition was not possible for these echoes. In this respect, a pelagic trawl would be the fishing gear of choice.

Biases associated with the detection of acoustic backscatter and its conversion to biomass tends to limit confidence in acoustic survey estimates as absolute measures of absolute abundance. However, an examination of these potential biases reveals that the majority of them should result in an underestimate of stock abundance (McQuinn and Lefebvre 1996). Therefore the results of these surveys should at least be taken as minimal or relative biomass estimates, comparable from year to year. If, however, we compare the spawning-stock biomasses estimated from these acoustic surveys with the spawning-stock biomass of western Newfoundland herring estimated from the virtual population analysis (McQuinn *et al.*, 1999), we find that they are very similar (Figures 5 and 6). This may not be surprising, given that the acoustic estimates are used to calibrate the VPAs. However, when we compare the spawning-stock biomass estimates for spring spawners from the acoustic survey with the VPA estimates calibrated using the index-fisherman abundance index only (1995-1998), the annual estimates are not significantly different for any of the 4 years (Figure 7) and, for the final two years, they are for all practical purposes, identical. Although there are several potential biases with these acoustic estimates, it is likely that they are insignificant in practice given that these two independent methods (VPA using catch rate index versus the acoustic survey) yield very similar results.

Acknowledgements

We greatly appreciate the expertise that we have received from Yves Samson and Daniel Thibault with the preparation and calibration of the acoustic equipment, from Jean-Louis Beaulieu and Philippe Schwab during the survey, and from Martin Montminy for the development of the CH1 data acquisition software. We particularly wish to thank the captains and crews of the *Frederick G. Creed*,

the *Matuna Mariner*, the *Silver Dolphin*, the *Eastern Pride* and the *Canada Park* for their participation in this survey, and especially to Ray Dunphy for co-ordinating all the logistical requirements for the purse-seine participation.

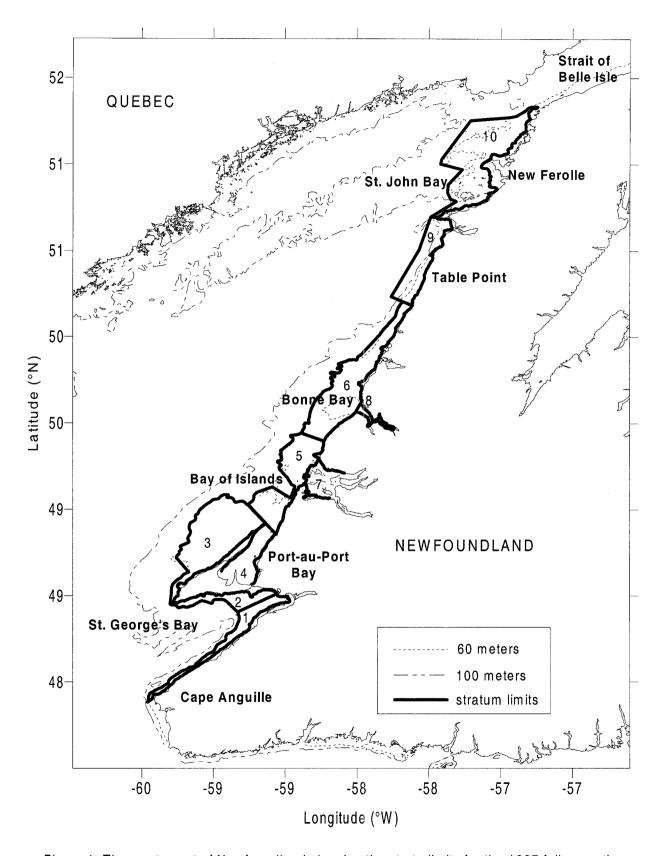

Figure 1. The west coast of Newfoundland showing the strata limits for the 1997 fall acoustic survey.

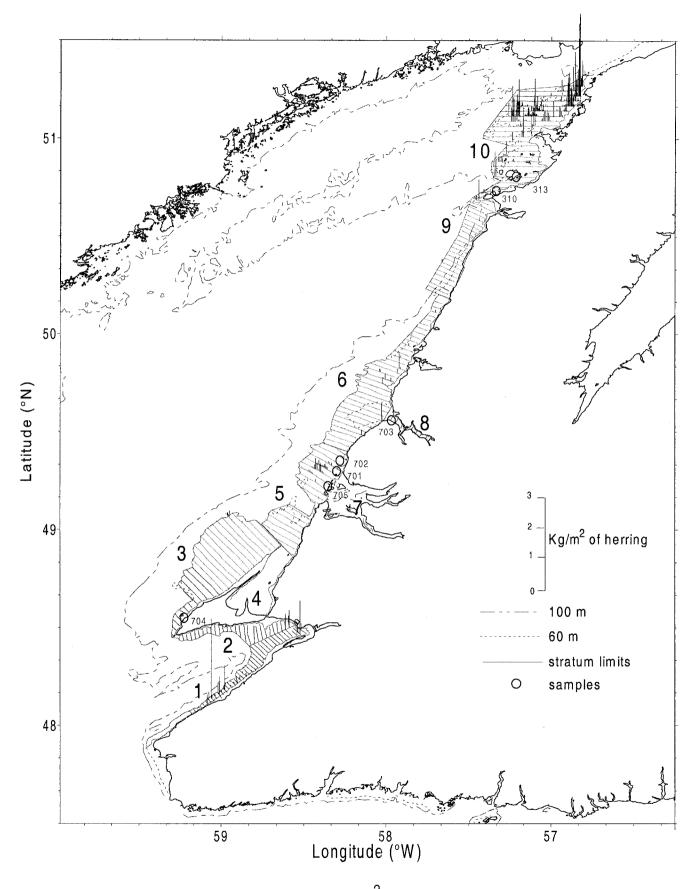

Figure 2. Distribution of herring density (kg/m²) along the west coast of Newfoundland in October, 1997 (stratum numbers and completed transects are indicated).

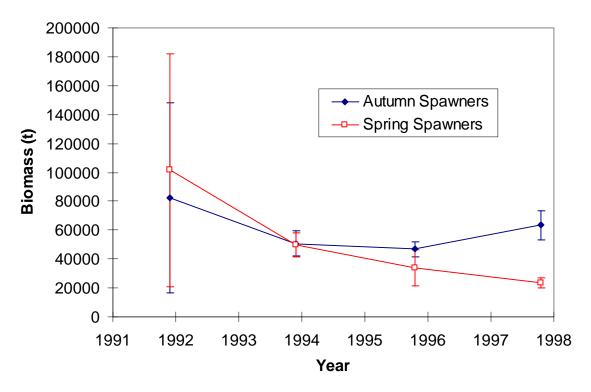

Figure 3. Total stock biomass and standard error estimates of spring- and autumn-spawning herring in NAFO division 4R from 1991 to 1997 from the biennial acoustic survey.

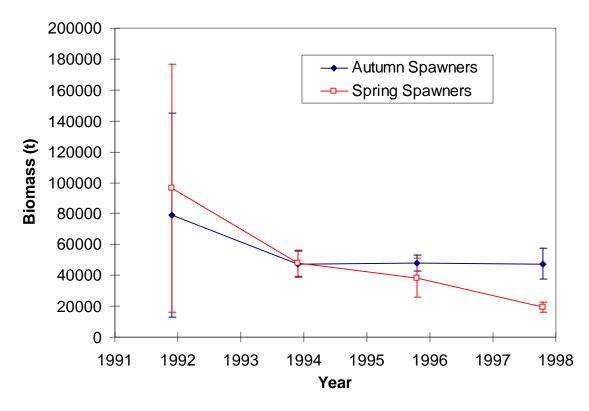

Figure 4. Spawning-stock biomass and standard error estimates of spring- and autumn-spawning herring in NAFO division 4R from 1991 to 1997 from the biennial acoustic survey.

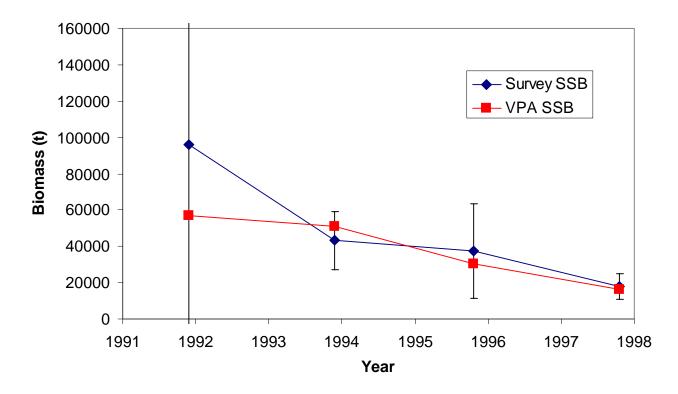

Figure 5. Spawning-stock biomass and 95% confidence interval estimates of spring-spawning herring in NAFO division 4R from 1991 to 1997 from the biennial acoustic survey compared to the virtual population analysis.

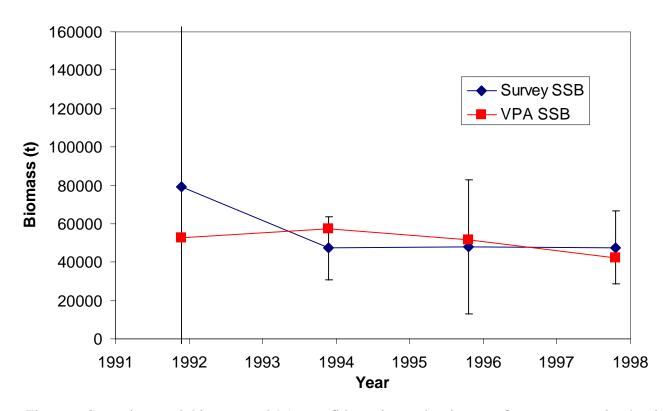

Figure 6. Spawning-stock biomass and 95% confidence interval estimates of autumn-spawning herring in NAFO division 4R from 1991 to 1997 from the biennial acoustic survey compared to the virtual population analysis.

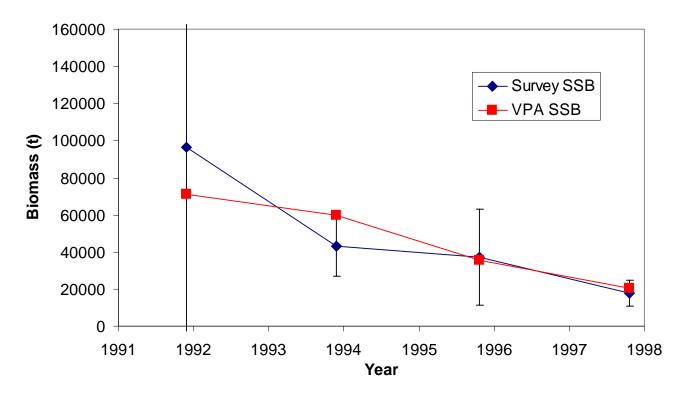

Figure 7. Spawning-stock biomass estimates of spring-spawning herring in NAFO division 4R from 1991 to 1997 from the biennial acoustic survey compared to the virtual population analysis (Index-Fisherman CPUE only).
