## Foreword

This series documents the scientific basis for the evaluation of aquatic resources and ecosystems in Canada. As such, it addresses the issues of the day in the time frames required and the documents it contains are not intended as definitive statements on the subjects addressed but rather as progress reports on ongoing investigations.

Research documents are produced in the official language in which they are provided to the Secretariat.

#### Abstract

Both conventional and satellite tagging studies indicate that blue sharks are widely distributed and highly migratory across both Atlantic Canada and the North Atlantic waters, with no evidence of year-round residency in Canadian waters.

There is no fishery-independent index of abundance for blue sharks in Canadian waters. Standardized catch rates from observers on pelagic longline vessels provide an index of local, short-term abundance, but do not appear to reflect population abundance. Population abundance in the North Atlantic appears to have decreased modestly since 1994.

The reported catch of blue sharks grossly underestimates both the actual catch (sum of landed catch and discards) and the catch mortality. In recent years, almost all catch mortality can be attributed to hooking and post-release mortality in pelagic longlines. Bycatch appears persistently along the edge of the continental shelf and in basins on the Scotian Shelf. Mortality from derbies and recreational shark fishing accounts for less than 3\% of overall fishing-related mortality in Canadian waters.

Blue sharks have negligible commercial value in Canada and large quantities (approximately 1400 mt annually) are discarded by commercial pelagic fisheries. Their persistence to this point is partly attributable to their productivity relative to other sharks species, the fact that few mature females are caught either in Canadian or American waters, and the relatively low overall Canadian contribution to overall population mortality. At present, fishing-related sources of mortality in Canadian waters appear to be sustainable, although large quantities of discards remain unutilized.

# Situation actuelle de la population de requin bleu (Prionace glauca) de l'Atlantique Nord dans les eaux canadiennes de l'Atlantique et menaces pesant sur celle-ci 

#### Abstract

RÉSUMÉ Les études de marquage traditionnel et par satellite indiquent que les requins bleus sont répartis sur une grande échelle et hautement migrateurs dans les eaux du Canada atlantique et de l'Atlantique Nord, sans preuve de résidence toute l'année dans les eaux canadiennes. Il n'existe pas d'indice d'abondance indépendant de la pêche pour les requins bleus dans les eaux canadiennes. Les taux de prises normalisés provenant des observateurs sur les palangriers de pêche pélagique fournissent un indice de l'abondance locale à court terme, mais ne semblent pas refléter l'abondance de la population. L'abondance de la population dans l'Atlantique Nord semble avoir légèrement diminué depuis 1994. Les prises déclarées de requins bleus sous-estiment nettement les prises réelles (somme des prises débarquées et des rejets) et la mortalité par capture. Au cours des dernières années, presque la totalité de la mortalité par capture peut être attribuée à l'hameçonnage et à la mortalité après rejet dans la pêche pélagique à la palangre. Les prises accessoires se font constamment le long du bord du plateau continental et dans les bassins du plateau néoécossais. La mortalité due aux tournois de pêche et à la pêche récréative au requin représente moins de $3 \%$ de la mortalité par pêche globale dans les eaux canadiennes. Les requins bleus ont une valeur commerciale négligeable au Canada et de grandes quantités (environ 1400 tm par année) sont rejetées par des pêches commerciales du poisson pélagique. Leur persistance à ce stade est en partie attribuable à leur productivité par rapport aux autres espèces de requins, au fait que peu de femelles matures sont capturées dans les eaux canadiennes ou américaines, et à la contribution générale assez faible du Canada à la mortalité de l'ensemble de la population. À l'heure actuelle, les sources de mortalité par pêche dans les eaux canadiennes semblent être durables, bien que de grandes quantités de rejets restent sous-exploitées.

## INTRODUCTION

The blue shark (Prionace glauca) is a large temperate and tropical pelagic shark species of the family Carcharhinidae that occurs in the Atlantic, Pacific and Indian oceans. The species is highly migratory, with tagging results suggesting that there is a single well-mixed population in the North Atlantic (Casey and Kohler 1991). In Canadian waters the blue shark has been recorded off southeastern Newfoundland, the Grand Banks, the Gulf of St. Lawrence, the Scotian Shelf and in the Bay of Fundy. At certain times of the year, it is probably the most abundant large shark species in eastern Canadian waters (Templeman 1963).

The inherent vulnerability of sharks and other elasmobranchs to overfishing and stock collapse is well documented. FAO's International Plan of Action for the Conservation and Management of Sharks (FAO 1998) concluded that many of the world's shark species are severely depleted, while an American Fisheries Society policy statement noted that most elasmobranch populations decline more rapidly and recover less quickly than do other fish populations (Musick et al. 2000). Indeed, the low productivity of elasmobranchs compared with teleosts is well established, which is largely a result of their low fecundity and late age at sexual maturation. Although the blue shark is among the more productive of pelagic shark species (Cortés 2000), a sustainable catch level or fishing mortality has never been calculated for blue sharks in the North Atlantic. Blue sharks are the primary bycatch species in most large pelagic fisheries, yet are not considered a desirable species by most nations. As a result, most of the sharks that are caught are then discarded, with some associated mortality. Discard statistics by all nations are poor (ICCAT 2009). An additional complication is the highly migratory nature of blue sharks, which splits their residency between the high seas and national waters.
In 2006, Blue Shark (Prionace glauca) was designated as Special Concern by the Committee on the Status of Endangered Wildlife in Canada (COSEWIC), with the following justification (see: COSEWIC 2006):

This species is a relatively productive shark (maximum age 16-20 years, mature at 4-6 years, generation time 8 years, 25-50 pups every two years), but as an elasmobranch, populations are susceptible to increased mortality from all sources including from human activities. The species is considered to have a single highly migratory population in the North Atlantic, of which a portion is present in Canadian waters seasonally. The abundance index which is considered to best represent the whole population has declined 60\% 1986-2000 but another index shows no longterm trend for the whole population 1971-2003. Indices of abundance in and near the Canadian waters show variable trends from no decline to $60 \%$ decline from the 1980s to early 2000s. There is evidence for a decline in mean length in longline fisheries in Canadian waters 19862003.The primary threat is bycatch in pelagic longline fisheries; although the threat is understood and is reversible, it is not being effectively reduced through management. Assessing the impact of bycatch on the population would benefit from better information on proportion of individuals discarded which survive. It appears that recent fishery removals from the North Atlantic have been several tens of thousands of tons annually. Estimated Canadian removals, a small proportion of the total, have been declining since the early 1990s and recently have averaged around 600 t per year.
The present document provides a summary of current population status and threats to this species in both Canadian waters and across the North Atlantic population. COSEWIC will use this information to aid in its next population status report for blue shark, which is scheduled for 2016.

## LIFE HISTORY CHARACTERISTICS

## REPRODUCTION

The blue shark is a viviparous species, with litters usually consisting of 25 to 50 pups after a gestation period of between 9 and 12 months. It is possible that there is a resting year after birth, but this remains unconfirmed (Snelson et al. 2008). Birth is believed to take place in the southwest or central Atlantic in the late winter or spring (Tavares et al. 2012; Vandeperre et al. 2014a). Newborn pups measure 35 to 50 cm in total length (TL). After copulation the females may retain and nourish the spermatozoa in the oviducal gland for months or years while awaiting ovulation.

In the northwest Atlantic, male length at 50\% maturity has been reported at 218 cm TL (Nakano and Stevens 2008), which is somewhat larger than that reported for the Mediterranean (Megalofonou et al. 2009) and north Pacific (Nakano and Stevens 2008). Female length at 50\% maturity appears to be about 220 cm TL in both the Atlantic and Pacific (Pratt 1979; Nakano and Stevens 2008). Age at maturity is estimated to be 4-6 years for males and 5-7 years for females worldwide (Nakano and Stevens 2008), but would be about 7 years in the Northwest Atlantic based on the growth curve of Skomal and Natanson (2003).
Size at sexual maturity in Canadian waters was assessed in examinations of more than 2000 blue sharks landed at shark tournaments (Campana et al. 2004). Fork length (FL) at maturity varied between $193-210 \mathrm{~cm}$ for males, with a length at $50 \%$ maturity of 201 cm . Mature females were seldom caught at shark tournaments and length at maturity could not be estimated.

## NATURAL MORTALITY

The instantaneous natural mortality rate $(M)$ has never been directly estimated in blue sharks. Therefore, various studies have inferred $M$ in blue sharks using meta-analysis of observed relationships between growth rate, mortality rate, and/or longevity. The inferred values for M range from 0.07 to 0.48 (Campana et al. 2004), with an overall mean of 0.23 . Since $M$ would be expected to vary inversely with growth rate, the importance of an accurate growth model is clear.

## AGE AND GROWTH

There are no well validated age and growth models for blue sharks. Skomal and Natanson (2003) used vertebral sections to estimate age, concluding that longevity was between 16 and 20 years. Growth rate based on whole vertebrae gave comparable results to those based on vertebral sections, but only until Age 8 (MacNeil and Campana 2002). In neither study was there evidence of sexually dimorphic growth before sexual maturity, although Skomal and Natanson (2003) noted a slightly reduced growth rate for mature males. Blue sharks to an age of 12 years, based on whole vertebrae, have been observed in the Mediterranean (Megalofonou et al. 2009), while a maximum age of 22 years has been observed in the Indian Ocean; this latter age was validated as accurate with bomb radiocarbon (Campana, unpublished).
Generation time, which is the average age of parents in the current cohort, is estimated as the age at which $50 \%$ of the females are mature plus $1 / \mathrm{M}$ (where $\mathrm{M}=0.23$; see above). Therefore, generation time is 11.3 years (or $7+1 / 0.23$ ).

## DISTRIBUTION, MIGRATION AND DESIGNATABLE UNITS

Blue sharks are known to be an abundant pelagic shark species in most of the world's temperate oceans. They are widely distributed in marine waters with a bottom depth greater
than about 50 m and have a strong association with temperatures of between 10 and $25^{\circ} \mathrm{C}$ (Nakano and Stevens 2008; Campana et al. 2011a).

## DISTRIBUTION IN CATCH

Commercial catch locations can provide an indication of a species' distribution, although it may not show the full extent. Figure 1 shows the commercial catch location of blue sharks observed by at-sea fishery observers operating in the DFO Maritimes Region between 1998 and 2014. In Atlantic Canada, blue sharks are widely distributed in offshore and off-shelf waters, with extension to the far northeast in association with the Gulf Stream. Distribution on many areas of the continental shelf however is not demonstrated in Figure 1, since most of the captures are associated with the offshore swordfish fishery operating in the region. Figure 2 shows the commercial catch location of blue sharks in the offshore of Newfoundland and Labrador, as recorded by at-sea fishery observers operating in the DFO Newfoundland and Labrador Region between 1980 and 2012. Gillnet, longline and trawl fisheries which target Atlantic cod (Gadus morhua), white hake (Urophycis tenuis), and monkfish(Lophius americanus) capture blue shark on the Grand Banks in NAFO Divisions 3LNO, and St. Pierre in NAFO Subdivision 3Ps. Catches in other fisheries, such as those that targeted swordfish, bigeye tuna and porbeagle, are found in areas off the shelf.

Blue sharks are rarely reported in the Gulf of St Lawrence and the western coast of Newfoundland by at-sea fishery observers operating in these areas.

## DISTRIBUTION AND MIGRATION FROM TAGGING STUDIES

The migration pattern of blue sharks in Canadian waters was analyzed on the basis of tag recaptures from four sets of tagging studies. A total of 2017 tags were applied to blue sharks in a Canadian tagging program carried out between 1961 and 1980 (Burnett et al. 1987). Most of the tags were applied before 1972, which makes this study most applicable to the early years of the longline fishery. With only 17 recaptures from this study, it was difficult to draw many conclusions. However, it was clear that at least some of the sharks migrated freely between inshore and offshore waters, and between Canadian and U.S. waters (Campana et al. 2004).
A second tagging study was carried out by the National Marine Fisheries Service of the U.S. in cooperation with Canadian fishers. This study applied 916 tags to blue sharks in Canadian waters between 1971 and 2002, with most of the tagging effort taking place after 1990. Most of the 188 recaptures in Canadian waters were tagged in the U.S.; a pattern which would be expected given that most of the tagging effort was concentrated in the U.S. (Figure 3; bottom panel). In contrast, most of the tags applied in Canadian waters were later recaptured in the central and eastern Atlantic, as far away as Africa (Figure 3; top panel).
A third ongoing tagging study, conducted by DFO's Shark Research Laboratory, in cooperation with recreational shark fishermen at annual shark derbies, has tagged 2374 blue sharks since 2006. Of the 54 recaptures to date, most have been recaptured in the central Atlantic (Figure 4).

A fourth tagging study was carried out using pop-up satellite archival tags (PSAT), which give a fishery-independent view of blue shark migration, since they do not require capture (Campana et al. 2011a). Of the 23 successful pop-ups, all blue sharks moved into warmer off-shelf waters to the east and south in the winter, often in association with the Gulf Stream (Figure 5).

Quite a few of the tag recaptures were made after periods at liberty of more than one year, but there did not appear to be any obvious tendency for recaptures to be made near the tagging location. Thus, there was no evidence of repeated annual returns to a particular location, as is often observed in tagged groundfish.

Although the four tagging studies extend over a period of more than 50 years, there is no indication of any change in blue shark distribution over that period.

## DESIGNATABLE UNITS

Both the commercial catch locations and the four tagging studies indicate that blue sharks are highly migratory, spend considerable amounts of time outside of Canadian waters on the high seas, and show no obvious signs of population differentiation in the Northwest Atlantic. This is consistent with published views that there is a single population of blue sharks in the North Atlantic (Vandeperre et al. 2014b).

## POPULATION TRENDS

There are no fishery-independent indices of abundance for the North Atlantic blue shark population. The only index of abundance for the population as a whole is that based on the average of numerous catch-per-unit-effort (CPUE) indices from national pelagic longline fleets, where blue sharks appear to be of intermediate vulnerability compared to other shark species in the North Atlantic (Cortes et al. 2010). The averaged ICCAT index for the North Atlantic shows no marked trend in relative abundance between 1958 and 1994, with a decline thereafter (ICCAT 2012). The net decline since 1958 was approximately $20-30 \%$. A population model based on the CPUE indices indicated that biomass in 2010 remained above biomass at maximum sustainable yield ( $\mathrm{B}_{\text {msy }}$ ) and that no overfishing was occurring, although the ICCAT report further acknowledged that the population model was highly uncertain.
Several regional indices of blue shark abundance are broadly consistent with the ICCAT assessment. Baum (2002) reported that CPUE derived from U.S. logbooks increased in the area surrounding the Grand Banks, the area of highest blue shark numbers, between 1986 and 1993, declining thereafter. The net decline in that region was $9.6 \%$ between 1986 and 2000. The net decline was $60 \%$ in the Northwest Atlantic as a whole between 1986 and 2000 (Baum et al. 2003; but see rebuttal by Burgess et al. 2005). A comparable analysis of U.S. pelagic longline CPUE, this time based on observer data, suggested that CPUE first increased and then decreased between 1992 and 2005, for a net decline of 53\% (Baum and Blanchard 2010).
In other regions of the Atlantic, Mejuto et al. (2008) reported that the CPUE of the Spanish longline fleet in the North Atlantic increased between 1997 and 2000, and then declined by 13\% to 2007. Similarly, Tavares et al. (2012) reported a significant decline in standardized CPUE off northeastern South America between 1998 and 2007.

## CATCH RATE OF BLUE SHARK IN CANADIAN WATERS

The catch rate of blue sharks in the recreational shark fishery is not a useful indicator of abundance largely because few records of small (and released) sharks are maintained (Campana et al. 2004). Therefore, catch rates in the shark derbies and non-derby recreational fishery were not estimated for this assessment.
Calculations of commercial catch rate (In-transformed kg/hook) were based on directed pelagic longline catches for swordfish in the months June to October from 1995 onwards, which account for most of the blue sharks caught in Atlantic Canada. All data came from the Maritimes Region At-Sea Observer Program and are thus considered more accurate than logbook data, at least after 1997. Between 1995 and 1997, certain Observers failed to report any blue sharks; therefore trips in those years where no blue sharks were reported were removed from the analysis. In addition, only vessels which fished at least 10 sets in at least 2 years were included. An initial full model, based on 1864 sets, identified many significant spatial and temporal factors
and their interactions, but there were too many null cells in the factor array to be useful (Table 1). A series of model simplications ended with a final generalized linear model (GLM) which included CFV (vessel identity) and year as significant factors (Table 2). Although the interaction term was also significant, the full model did not provide predictions for the year term and could not be used. Thus, only the main effects model was used for prediction.

The GLM of blue shark catch rate resulted in an estimated catch rate trend which largely paralleled that based on mean observed catch rates (Figure 6). There was no significant trend in CPUE between about 2001 and 2013. The year-to-year variability in the estimated trend was too large to be attributable to real changes in population abundance, and was more likely to reflect year-to-year differences in availability related to oceanographic conditions, the relatively low observer coverage, or both. As such, it is unlikely that Canadian blue shark catch rates by themselves can be used to monitor population abundance.

## BLUE SHARK HABITAT

Blue sharks are pelagic sharks seldom found over ocean bottom less than 50 m deep. PSAT tags applied to 23 blue sharks between 2003 and 2007 demonstrated that blue sharks remain in near-surface waters (less than 50 m ) for most of the summer and fall, moving into deeper waters near the end of November (Figure 7). Mean depth while on the continental shelf was 29 m . The temperature occupied ranged between $10-20^{\circ} \mathrm{C}$, with a mean of $15^{\circ} \mathrm{C}$ (Figure 7).

The summer/fall residency in surface waters, invariably associated with swordfish and tuna, makes this period one of high availability to large pelagic longline gear. On the other hand, the movement to deeper offshore water in late fall tends to reduce the interaction of blue shark with pelagic longline fisheries.

There are no known important habitats for blue sharks in Canadian waters. Mating, birth and nursery areas are all believed to be in international waters to the south and east (Tavares et al. 2012; Vandeperre et al. 2014a).

## THREATS

All known threats to the North Atlantic blue shark population are due to fishing, either within Canadian waters or elsewhere within the population range across the North Atlantic. With the exception of the recreational shark fishery, all blue sharks are caught as bycatch of other fisheries; primarily the pelagic longline fishery for swordfish and tuna. A substantial source of mortality is hooking and post-release mortality. These sources are addressed below.

## COMMERCIAL LANDINGS

Blue shark landings and/or nominal catch in the Canadian Atlantic (NAFO Areas 2-5) are known only for Canadian vessels landing their catch or for foreign vessels operating under 100\% observer coverage within the exclusive economic zone (EEZ). Landings have averaged about 10 metric tonnes (mt) per year since 2004 (Table 3). Only Canadian, Japanese and Faroese vessels are known to have caught significant quantities of blue shark in Canadian waters. In the Northwest Atlantic as a whole (north of Florida), mean reported catches are much larger, averaging about $20,000 \mathrm{mt}$ annually until 2010 (the last complete year of statistics). North Atlantic nominal catches are substantially larger, averaging over 37,000 mt since 2008. The marked increase in reported North Atlantic catches since 2007 is due to increased reporting of dead discards rather than any substantial increase in landings.

DFO Newfoundland and Labrador Region Zonal Interchange File Format (ZIFF) data contain very limited landings of blue shark (Figure 8). The landings in 1994 were due to unspecified longline fisheries. The landings in 1995 and 1996 were due to swordfish-directed longline fisheries. Landings in 2002 represent Atlantic cod and redfish (Sebastes sp.) fisheries. The increased landings in 2005 represent a bigeye tuna-directed longline fishery.

## OBSERVER BYCATCH

The Maritimes Region At-Sea Observer Program has maintained 100\% coverage of foreign fisheries in the Canadian zone since 1987, thus allowing accurate determinations of both nominal catch and bycatch. The Maritimes Region At-Sea Observer Program coverage of domestic pelagic longline vessels has been considerably less (approximately $5 \%$ since 2004). Nevertheless, Maritimes Region At-Sea Observer Program observations indicate that Canadian, Japanese and, in earlier years, Faroese longliners caught substantially larger numbers of blue sharks than would otherwise be known from nominal catch statistics (Table 4). Blue shark bycatch in fisheries other than that for large pelagics was much smaller, although the 1-2 mt observed on NAFO 4X groundfish longlines could add up to $20-60 \mathrm{mt}$ annually when pro-rated across non-observed fishing trips.

Observed catch and bycatch between 1990 and 1999 averaged about 250 mt annually, with most of that coming from Japanese vessels (Table 4). Since 1999, virtually all observed catch and bycatch has been caught and discarded by Canadian vessels.

The Newfoundland and Labrador Region At-Sea Observer Program coverage in some fisheries has been less than $5 \%$. However, as the only source of discard data in Newfoundland waters, it provides important information. Between 1980 and 2012, blue shark has been captured in gillnet, longline and trawl fisheries which target Atlantic cod, white hake, monkfish, as well as swordfish, bigeye tuna and porbeagle (Figure 9). In addition, blue shark are also captured in some trawl fisheries which target Atlantic cod and yellowtail flounder (Limanda ferruginea).

## ESTIMATION OF UNOBSERVED BLUE SHARK BYCATCH

To determine the magnitude of the blue shark bycatch in the various large pelagic fisheries, bycatch was estimated by country, fishery, quarter and year from the Maritimes Region At-Sea Observer Program observations made between 1986-2014, with bycatch defined as the summed weight of the kept and discarded blue sharks relative to the summed large pelagic catch (tuna, swordfish and porbeagle). The summed large pelagic catch accounted for virtually all of the catch, and its use in the estimation avoided problems associated with the species sought being unknown. The analysis was restricted to Canadian, Japanese and Faroese vessels, since they accounted for more than $99 \%$ of the blue shark catch. Bycatch in the foreign fisheries was fully observed, so estimation was used more to calculate bycatch proportion than bycatch weight for foreign vessels. Total pelagic catch for each cell was determined from ZIFF for Canadian vessels and from the Maritimes Region At-Sea Observer Program for foreign vessels. Full details on the estimation protocol are presented in Campana et al. (2011b).

Blue sharks dominated the bycatch of large pelagic longlines, accounting for $46 \%$ of total observed catch weight since the year 2000. Blue shark bycatch in the porbeagle fishery was substantially less, averaging 7\%. Since there were no consistent trends across years, the weighted mean proportion (weighted by number of observed sets) across years was used to estimate the Canadian bycatch. Therefore, each quarter and fishery was characterized by a unique bycatch proportion, but this proportion was maintained for all years. This method of calculation is considered to be less susceptible to sampling variability than was the year by year
method of Campana et al. (2002). In addition, the sum of the large pelagic catches was updated and revised from those of Campana et al. (2004).
Blue shark bycatch and proportions for each year and quarter in the Canadian tuna and swordfish fisheries are presented in Table 5. Bycatch ratios of blue shark to target species often exceeded $100 \%$. Annual bycatch estimates have averaged about 1400 mt annually since 2000, with an increasing trend largely due to increased catches of tunas and swordfish.

Blue shark bycatch in the pelagic longline fishery catches both immature and mature sharks, ranging from newborns to those over 3 m in length (Figure 10). The swordfish and tuna fisheries tend to catch slightly larger blue sharks than does the porbeagle fishery.

Blue shark bycatch also occurs in the groundfish fisheries, but is very small compared to that in the swordfish and tuna fisheries (Table 6; Figure 11).

Total blue shark bycatch in various fisheries in Newfoundland and Labrador was estimated based on observed bycatch and landings (Figure 12). In 1993, the total estimated bycatch peaked at 60 mt based on swordfish and tuna-directed fisheries. In recent years, bycatch of blue sharks has not exceeded 22 mt , and has averaged only 12 mt over the period 2002-2012. Most bycatch in recent years has occurred in groundfish-directed fisheries.

## HOOKING AND POST-RELEASE MORTALITY

Prior to 1994, most shark bycatch was killed by finning. After finning was banned in 1994, virtually all blue sharks caught with pelagic longlines in Canadian waters were discarded or released after capture. Many of these sharks are alive at the time of retrieval to the boat and continue to remain alive after release. However, a significant percentage of sharks die while on the hook (hooking or capture mortality), while a significant percentage of the live releases subsequently die due to stress or injury (post-release mortality). Hooking mortality can be measured by onboard observers, and has been assessed more carefully since 2010 as a result of additional training. However, post-release mortality requires continual monitoring through use PSAT tags (Campana et al. 2009).
Close to 20,000 blue sharks have been observed on large pelagic fishing vessels between 2010 and 2014 (Table 7). Of those where condition could be assessed at release, and assuming that moribund and shark-bit sharks were dead, the annual percentage of dead blue sharks ranged between $11-37 \%$, with an overall mean of $15 \%$. This value is slightly higher than the $12 \%$ observed value for the years 2001-2008 and slightly lower than the $20 \%$ value measured by biologists in a previous study (Campana et al. 2009).
Post-release mortality of blue sharks was measured in a previous study (Campana et al. 2009) and found to differ with the condition of the shark at release. Healthy, jaw-hooked sharks showed no mortality ( $n=10$ ), while injured sharks $(n=27)$ experienced a $33 \%$ mortality. Table 7 indicates that an annual percentage of 10-38\% of the assessed blue sharks were reported by observers as being injured at the time of release, with an overall mean of $25 \%$. Applying the $33 \%$ mortality rate to the $25 \%$ injury rate yields an estimated overall post-release mortality of live blue sharks of $8.25 \%$. When combined with a $15 \%$ hooking mortality, overall non-landed fishing mortality of blue sharks captured in the pelagic longline fishery is estimated at $23 \%$. According to the Observers who made the observations, this estimate of fishing mortality is likely a minimum estimate, since they noted that they often got only a quick glimpse of each blue shark as it was brought up to the rail and cut off, leaving only those that were badly injured or clearly dead being recorded as such.
Hooking and post-release mortality in the recreational shark catch-and-release fishery has not been measured, but is believed to be very low. A 10\% mortality rate was assumed here.

## BYCATCH DISTRIBUTION

The large pelagic fisheries in the northwest Atlantic all catch a broad range of desired catch and undesired bycatch, but blue shark bycatch in the pelagic longline swordfish fishery is by far the largest. To identify blue shark bycatch distribution and abundance in the Canadian swordfish fishery, observer data from swordfish or tuna trips on the Canadian longline fleet were analyzed to estimate blue shark catch proportions in relation to the sum of target catch plus bycatch weight. Target species were defined as swordfish, bigeye, yellowfin and albacore tuna. The 20 most important bycatch species included the sharks, bluefin tuna, marlins, turtles and several other minor species. All catches were filtered to remove sets where total catch was less than 200 kg (approximately $9 \%$ of sets). Observations were then grouped into 5 year periods, with spatial aggregation at 30 minute blocks.

Large pelagic catches tended to be largest along the edge of the Scotian and Newfoundland shelves, offshore of the shelves in the Gulf Stream, and within Emerald and Lahave basins (Figure 13). Blue shark bycatch proportions tended to be largest where total catch was largest, except near the entrance to the Laurentian Channel. Seasonally, blue shark bycatch tended to be largest in the October to December time period (Figure 14).

## RECREATIONAL SHARK FISHERY AND SHARK TOURNAMENTS (DERBIES)

Federal regulations state that the recreational shark fishery is to be catch and release only, with the exception of shark derbies. Prior to 2006, no sharks less than 180 cm ( 6 feet) in length could be landed. Beginning in the summer of 2006, rules for all derbies were changed such that all blue sharks less than 240 cm ( 8 feet) were to be released alive, preferably after tagging. Tagging was voluntary, but was strongly encouraged by DFO Science. Total derby landings have been capped at 20 mt .

All shark derbies in Atlantic Canada are currently located in Nova Scotia. On average, there have been 5-6 derbies held each year between late July and mid-September. Fishing locations are primarily located on the continental shelf and on Georges Bank (Figure 15).
The weight of sharks landed at recreational shark tournaments has increased from around 4 mt in 1993, the first year of the derbies, to an average of 11 mt since 2006 (Table 8). These figures are undoubtedly underestimates of actual fishing mortality, since anecdotal evidence indicates that some fishermen retain and kill blue sharks throughout the derby fishing period until or unless a larger shark is caught. Although shortfin mako (Isurus oxyrinchus), thresher (Alopias vulpinus), and porbeagle (Lamna nasus) have all been caught at derbies, blue sharks account for $99 \%$ of all landings.
The size and sex composition of blue sharks landed at the derbies has changed markedly since the minimum size regulations were changed at the beginning of 2006. Prior to 2006, the length composition was dominated by immature sharks of both sexes with an overall sex ratio of almost exactly $50 \%$ (Figure 16). After 2006, $85 \%$ of the sharks landed were males, most of them mature.
Blue shark recreational catch outside of derbies is infrequently recorded in recreational fishing logs. Previous estimates suggested that non-derby catches (and releases) were approximately 12.5 mt per year (Campana et al. 2004).

## EXPLOITATION RATE FROM TAG-RECAPTURES

The exploitation rate of blue sharks in Canadian waters was estimated through Petersen analysis of tag recaptures. Estimates of commercial exploitation rate were not possible given the very low reporting rate of a discarded species by commercial fishermen. To provide an estimate of exploitation rate which is unaffected by reporting rate, we restricted the analysis to
the recreational fishery, which is highly motivated to report any recovered tags since they do almost all of the tagging. Estimates of exploitation rate $(E)$ were calculated as:
$E=R /\left(T^{*}\left(1.0-M_{t}\right)^{*} \exp (-(\mathrm{L}))^{*} \exp \left(-\left(\mathrm{M}_{\mathrm{n}}^{*} \mathrm{P}\right)\right)\right)^{*} \mathrm{RR}$, where
$\mathrm{R}=$ Number of tags recovered
$\mathrm{T}=$ Number of tags
$\mathrm{M}_{\mathrm{t}}=$ Tag mortality
$\mathrm{L}=$ Tag loss
$\mathrm{M}_{\mathrm{n}}=$ Natural mortality
$P=$ Period relative to 1 year
$R \mathrm{R}=$ Tag reporting rate

Estimates of natural mortality ( $\mathrm{M}_{\mathrm{n}}=0.22$ ) and tag loss ( $\mathrm{L}=0.11$ ) were adopted from the NMFS tagging program on blue sharks (Silva 2008). We assume no tagging mortality ( $\mathrm{M}_{\mathrm{t}}=0.0$ ) associated with the scientific and recreational tagging in this study and 100\% reporting rate (RR $=1.0)$ by recreational fishermen, both within and outside of derbies. Annual exploitation rates were calculated using only those recoveries occurring within 365 days of tagging ( $\mathrm{P}=1.0$ ). Annual exploitation rates were transformed to instantaneous fishing mortality rates ( $F$ ) as:

$$
F=\ln (1.0-E)
$$

A total of 2374 Floy tags were applied to blue sharks by recreational fishermen between 2006 and 2014, of which 13 were recaptured by recreational fishermen within Canada (Table 9). An additional 41 tags were recaptured by commercial fishermen or outside of Canadian waters, largely by Spanish longliners fishing in the central Atlantic. Calculated exploitation rates by recreational fishermen within Canada ranged between 0 and $2.3 \%$ annually, with an overall mean of $0.3 \%$ (Table 10). Exploitation rate by foreign longliners was considerably higher, especially in the first few years of the tagging program. These results suggest that recreational fishing mortality within Canadian waters is very low to the point of being undetectable - about $1 \%$ that of the natural mortality rate. Similar calculations applied to 916 tags applied by Canadian recreational fishermen to blue sharks in Canadian waters as part of the NMFS tagging program produced a comparable mean exploitation rate of $0.78 \%$ between 1992 and 2002 (Campana et al. 2004).

Tag recaptures by shark derby participants ( $\mathrm{R}=3$ ) compared to non-derby recreational fishermen and charters $(R=4)$ were of comparable magnitude, consistent with previous calculations suggesting that derby and non-derby recreational exploitation rates are similar (Campana et al. 2004).
It is important to note that the $0.3 \%$ estimate of exploitation rate mentioned above reflects only the Canadian recreational exploitation rate and not that on the population as a whole.

## TOTAL CATCH MORTALITY

Total estimated annual blue shark catches, discards and catch mortality in Canadian waters are shown in Table 11. Discards from the Canadian large pelagic fisheries constituted the largest proportion of blue sharks caught in Canadian waters since 1986. However, total estimated catch mortalities, based on the discard mortalities presented earlier, are lower, averaging around 400 mt per year in recent years (Table 11; Figure 17). The proportion of catch mortality contributed by derby and recreational shark fishing was small, averaging less than $3 \%$ of the total catch mortality in recent years.

## SUSTAINABLE MORTALITY LEVEL FOR BLUE SHARKS IN CANADIAN WATERS

Blue sharks in Canadian waters are part of a North Atlantic-wide population, and thus are subject to assessment and regulation by ICCAT. Although ICCAT has completed a stock assessment for blue sharks, which ICCAT itself acknowledges as uncertain, no reference points have been set and there are no catch or mortality regulations (ICCAT 2009, 2012). National allocations have been set for many of the tuna and swordfish species, but such do not exist for any of the sharks other than porbeagle. At present therefore, there are no limits or estimates of sustainable mortality in place for blue sharks in Canadian waters.

There are several possible approaches to calculating national allocations of a transboundary fish stock, one of which is the use of national catch (landings plus discards) histories. However, the use of catch histories has no scientific basis for determining biological reference points, and appears particularly unsuitable for a non-retained bycatch species for which few countries have reported estimates of discard mortality. As an example of the arbitrarity of catch histories for blue shark, Canada's reported blue shark catch and discard mortality would be 0\% of the North Atlantic reported blue shark longline catch if based on the most recent five years, $0.35 \%$ if based on the last 7 years, and $1.3 \%$ if based on the most recent 10 years (ICCAT 2014). A calculation based on the 10 years leading up to the last ICCAT stock assessment in 2008 would yield $3.1 \%$. Catch histories based on landings, as opposed to discard mortalities for which only Canada has reported statistics, would be very close to 0\% for Canada. Clearly, catch histories based on reported blue shark catches would not provide any meaningful information for determining if Canadian blue shark discard mortalities are biologically sustainable.
Another possible, more scientifically defensible approach to calculating sustainable mortality levels within Canada is to determine the sustainable mortality of the entire North Atlantic blue shark population, and then pro-rate it based on Canada's share of the catch of targeted ICCAT fisheries which also catch blue sharks. The catch statistics for valued (targeted) ICCAT species are considered to be much more accurate than those of discarded species, thus making them far more useful in calculations.

The most recent stock assessment for the North Atlantic blue shark stock was conducted in 2008, using data up to the end of 2007. This assessment provided explicit estimates of Maximum Sustainable Yield (MSY) yield only from the Bayesian surplus production model (ICCAT 2009, 2012). The base case MSY yield from that model was $9,334 \mathrm{mt}$, with a range of 5,664 to $24,659 \mathrm{mt}$. Given that recent blue shark catches have averaged around $60,000 \mathrm{mt}$, it is clear that these MSY estimates, based on the Bayesian model, provide a pessimistic view of stock status. Unfortunately, projections of MSY yield were not made from the alternative, more optimistic model tabled in the assessment. Therefore, the Bayesian model MSY estimates were not used, but rather estimated from model-estimated ratios as follows below.
Virgin biomass ( $\mathrm{B}_{0}$ ) of North Atlantic blue sharks was estimated to fall in the range of 861,081$1,923,000 \mathrm{mt}$ (ICCAT 2009). $\mathrm{B}_{2007} / \mathrm{B}_{0}$ was reported as being in the range of $0.67-0.93$, while $\mathrm{B}_{2007} / \mathrm{B}_{\text {msy }}$ was reported as 1.87-2.74 (ICCAT 2012). $\mathrm{F}_{\text {msy }}$ was reported as 0.15 , which corresponds to an exploitation rate of $14 \%$. Rearranging the above equations to calculate $\mathrm{B}_{\mathrm{msy}}$, and multiplying the exploitation rate at MSY by $\mathrm{B}_{\text {msy }}$, blue shark catch at MSY was estimated for all combinations of upper and lower values, producing eight estimates of MSY which span the highest possible and lowest possible values. These estimates lay in the range of 29,330 to $133,200 \mathrm{mt}$, with an overall mean of $69,800 \mathrm{mt}$. While the legitimacy of this analytical derivation was confirmed by the ICCAT scientist who ran all of the blue shark assessment models ( E . Cortés, National Marine Fisheries Service, Panama City, FL, USA, pers. comm.), he also noted that it was not appropriate to include the output of the [more optimistic] age-structured models in any calculations, since there is no simple way to extract MSY from the model that was used.

Implicit in this statement is that MSY yield without the inclusion of the age-structured models would result in the low 9,334 mt value reported earlier.

More than $96 \%$ of the reported blue shark catches in the North Atlantic are caught by pelagic longlines, indicating that overall blue shark MSY yield can be largely attributed to this fishing gear. Of the pelagic longline species managed by ICCAT, Canada fishes several target species whose pelagic longline fisheries also catch blue sharks: swordfish, albacore, bigeye, yellowfin and bluefin tuna. In 2007, the year of the last full blue shark assessment, the Canadian catch (including dead discards) of swordfish was 1,387 mt of the total North Atlantic longline catch (plus discards) of $11,748 \mathrm{mt}$. Equivalent values for longline-caught North Atlantic albacore ( 27 mt of 3237 mt ), Atlantic bigeye ( 144 mt of $46,232 \mathrm{mt}$ ), and western Atlantic yellowfin ( 276 mt of $13,557 \mathrm{mt}$ ) were based on smaller Canadian catches, as was the 55 mt of Canadian bluefin allocated to longline bycatch (out of a total western bluefin longline catch of approximately 600 mt ). Despite the fact that Canada's allocation of the tuna species is relatively small, blue sharks are caught throughout the North Atlantic and thus the blue shark MSY catch must be apportioned across all countries fishing pelagic longlines in the North Atlantic. For example, even if Canada was allocated and caught $100 \%$ of the North Atlantic swordfish quota, it wouldn't mean that they were entitled to $100 \%$ of the blue shark MSY, since blue sharks are caught in large numbers by other countries fishing tunas. In 2007, Canada's swordfish/tuna catch was $2.5 \%$ of the total North Atlantic swordfish/tuna longline catch. Applying this percentage to the range of blue shark MSY values would result in a Canadian portion of blue sharks of between $733-3330 \mathrm{mt}$, with an overall mean of 1550 mt . This approach assumes that the proportion of blue sharks relative to each of the five targeted ICCAT species are similar, and that the proportion is spatially invariant throughout the North Atlantic. These assumptions are unlikely to be correct, but the same assumptions are made by ICCAT in estimating blue shark catch throughout the Atlantic Ocean (ICCAT 2009). Based on this approach, blue shark mortality associated with fishing (i.e. landings, dead discards and post-release mortalities) of less than about 1550 mt annually should be sustainable in Canadian waters. Thus, the recent annual catch mortalities of about 400 mt would be considered sustainable under this approach, although the analytical uncertainties around the estimated range of sustainable levels of 7333330 mt indicate that catch mortalities may be close to the lower range of the sustainable level.

## DISCUSSION

Several conclusions concerning blue shark distribution, status and threats can be reached based on the analyses reported in this study.
Both conventional and satellite tagging studies indicate that blue sharks are widely distributed and highly migratory across both Atlantic Canada and the North Atlantic waters, with no evidence of year-round residency in Canadian waters.
There is no fishery-independent index of abundance for blue sharks in Canadian waters. Standardized catch rates from observers on pelagic longline vessels provide an index of local, short-term abundance, but do not appear to reflect population abundance. Population abundance in the North Atlantic appears to have decreased modestly since 1994.
The reported catch of blue sharks grossly underestimates both the actual catch (i.e. sum of landed catch and discards) and the catch mortality. In recent years, almost all catch mortality can be attributed to hooking and post-release mortality in pelagic longlines. Mortality from derbies and recreational shark fishing accounts for less than 3\% of overall fishing-related mortality in Canadian waters. Canadian sources of blue shark mortality remain a small percentage of total (international) mortality to the North Atlantic population.

Blue sharks have negligible commercial value in Canada and are discarded in large quantities, about 1400 mt annually, by Canadian commercial pelagic fisheries. The species persistence to this point is partly attributable to its productivity relative to other shark species, the fact that few mature females are caught either in Canadian or American waters, and the relatively low overall Canadian contribution to overall population mortality. At present, fishing-related sources of mortality in Canadian waters appear to be sustainable, although large quantities of discards remain unutilized.

## ACKNOWLEDGEMENTS

The authors thank Art Gaeten of Blue Shark Fishing Charters for providing access to his detailed catch records. Ross Jones, Mike James and Michael Eagles provided helpful comments on the manuscript.

Notes:

1. Canada is from DFO Zonal Statistics File and shark derby statistics.
2. Japan, Faroes, other countries in Canadian Atlantic are from DFO Maritimes \& Newfoundland and Labrador Observer programs (excludes discards).
3. NW Atlantic landings from countries other than Japan are from ICCAT statistics for area 92 until 1999.
4. Japan in NW Atlantic represents nominal catch of unspecified sharks and rays from FAO Statistics.
5. North Atlantic (plus Mediterranean) landings from ICCAT.

Table 4. Catch and discards (mt) of blue sharks in Canadian waters as observed by at-sea observers.

| 2002 | 19 | 13 | 0 | - | - | - | 1219 |

${ }^{1}$ Catch and release fishery, excluding derbies; 2001-2005 estimated from rec logs and phone survey:

- before 2001 assumed to be 0.66 of derby catches based on tag recaptures and 2002-2003 ratios.
- 2006+ assumed to be equal to derby catches based on recent tag recaptures.
${ }^{2}$ Canadian landings only; Maritimes, Newfoundland and Labrador.
${ }^{3}$ Maritimes Region At-Sea Observer Program estimates of all foreign kept catch.
$\ddagger$ Maritimes Region At-Sea Observer Program estimates of all foreign discarded catch.
* Taken from Table 6 and Figure 12; sum of estimated bycatch from all Canadian fisheries.
** Sum of landed catches, plus hooking and post-release mortality from Canadian fisheries:
- foreign discards prior to 1994 assumed to be dead due to finning.

## FIGURES

Drosameo Whitul bata Certre fiov 102014
Figure 1. Observed blue shark catch locations onboard all commercial fishing vessels between 1998 and 2014 as observed by at-sea fishery observers operating in the DFO Maritimes Region.

Figure 2. Blue shark commercial catch locations between 1980 and 2012 as recorded by at-sea fishery observers operating in the DFO Newfoundland and Labrador Region.

Figure 3. Blue sharks tagged or recaptured between 1971 and 2002 in Canadian waters under the U.S. National Marine Fisheries Service (NMFS) tagging program.

Figure 4. Recaptures of blue sharks tagged between 2006 and 2014 in Nova Scotia shark derbies.

Figure 5. Blue shark pop-up satellite archival tags (PSAT) tagging and pop-up locations as shown in Campana et al. (2011). Map shows tagging ( $($ ) and pop-up ( $\bullet$ ) locations for 23 blue sharks tagged off the eastern coast of Canada between 2003 and 2007. Pop-up symbols are coloured to match the corresponding tagging symbol. Month of pop-up indicated by number.

Figure 6. Predicted (line) and observed (open circles) generalized linear model (GLM) catch rate index (kg/hook) for blue sharks caught and observed in the June-October Swordfish fishery from 1995 to 2013.

Figure 7. Depth (top panels) and temperature ( ${ }^{\circ}$ C) (bottom panels) occupied by blue sharks while in Canadian coastal waters as recorded by pop-up satellite archival tags (PSAT) tags. Bars represent mean $\pm 1$ SE.

Figure 8. Total DFO Newfoundland and Labrador Region Zonal Interchange File Format (ZIFF) landings (kg) for blue shark, by gear type (gillnets or longlines), in NAFO Divisions 3LNO and NAFO Subdivision 3Ps.

Figure 9. DFO Newfoundland and Labrador Region At-Sea Observer Program observed catch (kg) of blue shark by fishery in NAFO Divisions 3LNO and NAFO Subdivision 3Ps from 1980-2012.

Figure 10. Length frequency (cm) of blue sharks in the swordfish/tuna (top panel) and directed shark (Porbeagle) (bottom panel) longline fisheries, based on Observer data from the DFO Maritimes Region.

Figure 11. Estimated total Canadian blue shark discards (mt) by fishery from 1996-2014.

Figure 12. Estimated total catch ( $m t$ ) of blue shark in NAFO Divisions 3LNO and NAFO Subdivision 3Ps from 1988 to 2012. Observed bycatch was pro-rated by total landings. Catch is plotted by directed species and gear type (GN=gillnet, $L L=$ longline).

Figure 13a. Observed blue shark catch proportions in the Canadian large pelagic longline fishery, aggregated in 5-year blocks. Symbol size indicates the mean catch weight (kg) of all target and major bycatch species.

Figure 13b. Observed blue shark catch proportions in the Canadian large pelagic longline fishery, aggregated in 5 -year blocks. Symbol size indicates the mean catch weight ( kg ) of all target and major bycatch species.

Figure 14a. Observed blue shark catch proportions in the 2008-2013 Canadian large pelagic longline fishery, aggregated by season. Symbol size indicates the mean catch weight (kg) of all target and major bycatch species.

Figure 14b. Observed blue shark catch proportions in the 2008-2013 large pelagic longline fishery, aggregated by season. Symbol size indicates the mean catch weight (kg) of all target and major bycatch species.

Figure 15. Reported fishing locations by participants at shark fishing derbies in Nova Scotia since 2000.

Figure 16. Length distribution (cm) of blue sharks landed at shark derbies before and after 2006, the year that minimum landing size was increased.

Figure 17. Total catch mortality ( $m t$ ) by source for blue sharks caught in Canadian waters from 19962014.
