Canadian Technical Report of Hydrography and Ocean Sciences

Technical reports contain scientific and technical information that contributes to existing knowledge but which is not normally appropriate for primary literature. The subject matter is related generally to programs and interests of the Ocean Science and Surveys (OSS) sector of the Department of Fisheries and Oceans.

Technical reports may be cited as full publications. The correct citation appears above the abstract of each report. Each report is abstracted in *Aquatic Sciences and Fisheries Abstracts* and indexed in the Department's annual index to scientific and technical publications.

Technical reports are produced regionally but are numbered nationally. Requests for individual reports will be filled by the issuing establishment listed on the front cover and title page. Out of stock reports will be supplied for a fee by commercial agents.

Regional and headquarters establishments of Ocean Science and Surveys ceased publication of their various report series as of December 1981. A complete listing of these publications is published in the *Canadian Journal of Fisheries and Aquatic Sciences*, Volume 39: Index to Publications 1982. The current series, which begins with report number 1, was initiated in January 1982.

Rapport technique canadien sur l'hydrographie et les sciences océaniques

Les rapports techniques contiennent des renseignements scientifiques et techniques qui constituent une contribution aux connaissances actuelles, mais qui ne sont pas normalement appropriés pour la publication dans un journal scientifique. Le sujet est généralement lié aux programmes et intérêts du service des Sciences et levés océaniques (SLO) du ministère des Pêches et des Océans.

Les rapports techniques peuvent être cités comme des publications complètes. Le titre exact paraît au-dessus du résumé de chaque rapport. Les rapports techniques sont résumés dans la revue *Résumés des sciences aquatiques et halieutiques*, et ils sont classés dans l'index annuel des publications scientifiques et techniques du Ministère.

Les rapports techniques sont produits à l'échelon régional, mais numérotés à l'échelon national. Les demandes de rapports seront satisfaites par l'établissement auteur dont le nom figure sur la couverture et la page du titre. Les rapports épuisés seront fournis contre rétribution par des agents commerciaux.

Les établissements des Sciences et levés océaniques dans les régions et à l'administration centrale ont cessé de publier leurs diverses séries de rapports en décembre 1981. Une liste complète de ces publications figure dans le volume 39, Index des publications 1982 du *Journal canadien des sciences halieutiques et aquatiques*. La série actuelle a commencé avec la publication du rapport numéro 1 en janvier 1982.

ABSTRACT

R.H. Loucks Oceanology Limited, Discovery Consultants Limited and Brian Petrie. 1991. Analysing for climatological information in the long term temperature monitoring program sea temperature time series. Can. Tech. Rep. Hydrogr. Ocean Sci. No. 132: viii + 209 pp.

Motivated both by fisheries researchers and aquaculturists, the Long-Term Temperature Monitoring Program (LTTMP) has produced nearshore temperature time series from a variety of sites in Atlantic Canada since 1967. On the order of 100,000 instrument-days of data have been digitized at 4-hour intervals. In this study, these data were re-edited and summarized in time and space to monthly averages over 35 'Unit Areas' which correspond to inshore fishing zones from northern Newfoundland through the Gulf of St. Lawrence to the Bay of Fundy, each separated into shallow (depth < 12m) and deep (depth \geq 12m) ranges. These time series of monthly temperatures have been used to derive monthly mean temperatures, variance and anomalies, to determine the correspondence with sea-surface temperature climatology from 'ship-of-opportunity' data, for patterns of variance, and for spatial scales of correlation.

In addition to the expected annual temperature variation, a consistent seasonal pattern appears in the monthly total variances. These are peaked in spring and autumn. The warming/cooling trends in spring/autumn months enhance the total variance and account for most but not all of the double-peak pattern.

Interannual variances, reflecting climatic trends, are significant in some of these time series. Spatial scales of variability are small (about 100 km) for the shallow depth ranges in the Gulf of St. Lawrence, on the east coast of Newfoundland and the Atlantic coast of Nova Scotia. Elsewhere, the spatial scales are less than the average station separation.

Although data coverage seems sparse, especially in winter, and although winter records tend to be most valuable for both aquacultural and climatological reasons, it is recommended that a sampling design analysis be made first to determine the cost/effectiveness of obtaining more winter data. A sampling design analysis could rationalize the program objectives, the space scales prevailing, and the budget so that the necessary number of winter sites could be identified.

Two final recommendations are that this data base be further analyzed using an empirical orthogonal function treatment for climatic patterns and using statistics of extremes for the return period of various extreme temperature episodes.

RÉSUMÉ

R.H. Loucks Oceanology Limited, Discovery Consultants Limited and Brian Petrie. 1991. Analysing for climatological information in the long term temperature monitoring program sea temperature time series. Can. Tech. Rep. Hydrogr. Ocean Sci. No. 132: viii + 209 pp.

Promu autant par des spécialistes des pêches que par des aquicultrices, le Programme de contrôle de la température à long terme (PCTLT) a produit des séries chronologiques de températures littorales à partir de divers sites du littoral canadien de l'Atlantique depuis 1967. Environ 100 000 jours-instruments de données ont été numérisés à des intervalles de 4 h. Dans cette étude, ces données ont été remises en forme et ramenées à des moyennes mensuelles, dans le temps et dans d'espace, sur 35 "unités de superficie" qui correspondent à des zones de pêche côtière allant du nord de Terre-Neuve à la baie de Fundy en passant par le golfe St-Laurent, chacune étant répartie selon que la profondeur est faible (<12 m) ou grande (\geq 12 m). Ces séries chronologiques de températures mensuelles ont été utilisées pour établir des températures moyennes, des variances et des anomalies mensuelles, pour déterminer la correspondance avec la climatologie basée sur des données de température de la surface de la mer provenant de "navires de passage", en ce qui a trait aux tendances des variances et aux échelles spatiales de corrélation.

Aux variations de température annuelles prévues semble s'ajouter un comportement saisonnier systématique des variances totales mensuelles, lesquelles atteignent des maximums au printemps et à l'automne. Les tendances au réchauffement/refroidissement durant les mois du printemps et de l'automne ajoutent à la variance totale et expliquent en grande partie le comportement à deux maximums.

Les variances interannuelles, à l'image des tendances climatiques, sont importantes dans certaines de ces séries chronologiques. Les échelles de variabilité sont faibles (environ 100 km) pour les faibles profondeurs dans le golfe St-Laurent, sur la côte est de Terre-Neuve et sur la côte de la Nouvelle-Écosse tournée vers l'Atlantique. Ailleurs, les échelles spatiales sont inférieures à l'espacement moyen des stations.

Même si la couverture des données semble éparses, surtout en hiver, et que les enregistrements d'hiver ont tendance à être des plus utiles pour des raisons tant aquicoles que climatologiques, il est recommandé de faire une analyse de plan d'échantillonnage pour déterminer s'il est rentable de recueillir plus de données l'hiver. Une telle analyse permettrait de rationaliser les objectifs du programme, les échelles spatiales retenues et le budget de manière à pouvoir identifier le nombre requis de sites d'hiver.

Deux recommandations finales proposent d'analyser davantage cette base de données pour déterminer les tendances climatiques au moyen d'un traitement empirique par fonctions orthogonales et la période de récurrence des divers épisodes de température extrêmes à l'aide de statistiques des extrêmes.

Introduction

Long-term sea temperature series have been seen by oceanographers as valuable climatic indicators and have been collected along the Atlantic Coast since early this century. First there was the network of lighthouses, lightships and research stations (parts of which remain active today) which measured sea temperatures daily from the Gulf of St. Lawrence to St. Andrews, New Brunswick. Off St. John's, Newfoundland temperature and salinity observations have been made at 'Station 27' for several decades. These data have yielded insights on climatic variability.

Complementing these nearshore measurements are ship observations of sea-surface temperature. Since the 1940's merchant ships' crewmen have voluntarily measured and reported sea surface temperature. Trites (1982) has prepared a decadal analysis of the ship-of-opportunity data for the period 1970–1979, and a year-by year interpretation annually through the mid-1980's (e.g. Trites and Drinkwater, 1983). Recently, these 'ship-of-opportunity' data (1950–1980) have been analyzed for the Canadian Atlantic Shelf by compiling monthly average temperatures for some twenty-four shelf and offshore regions. Thompson *et al.* (1988) have shown that winter sea surface temperature anomalies over the East Coast of Canada have spatial scales of order 1000 km and are related to anomalies of winter winds. Further it was found that summer sea surface temperatures over the shelf are related to those in the previous winter.

Since 1967, nearshore sea temperatures have been recorded in Atlantic Canada using Ryan Thermo-graph Recorders. In 1978, through the initiative of scientists at the St. Andrew's Biological Station, the effort to gather coastal temperature data was coordinated into the Long Term Temperature Monitoring Program (LTTMP). The opportunity now exists to process these baseline data for the following purposes:

- a) To consolidate the T data from specified nearshore areas in order to obtain long time series;
- b) To determine the annual cycles of T for the nearshore areas;
- c) To determine the monthly standard deviations of T;
- d) To produce monthly T anomaly time series;
- e) To conduct a preliminary investigation of the spatial scales of the anomaly fields;
- f) To attempt to relate these anomaly fields to other long time series such as the offshore temperature observations and river runoff; and, finally,
- g) To make recommendations on the future directions of the program.

These time series and data products should prove useful for studies examining the climate of the coastal ocean, investigations of processes such as the response to low frequency meteorological forcing, the assessment of nearshore locations for aquaculture and the examination of long term fisheries changes.

Approach and Results

Thermograph records are grouped by NAFO fishing areas (Figure 1) and depth range order to compute statistical products such as averages, the components of variance, and correlations. The depth ranges are designated as shallow ($0 < z < 12$ m) and deep ($z \geq 12$ m), where z is the moored depth of the instrument.

Within each group, distinction is made between those records which resemble neighbouring records and those which are obviously disparate. Reasons underlying the occurrence of any disparate records are noted where possible, e.g., sited near a river mouth or in a shallow protected bay. An attempt was made to consolidate records with appeared to represent a broad area. These series — one from each Unit Area for each different depth range sampled over the long term — form the data base for subsequent analyses.

By rough estimate, some 100,000 – 200,000 instrument-days of temperature measurements have been processed, leading to some 70 (35 Unit Areas × 2 depth-ranges), multi-year (but gapped) time series of monthly average temperature. The instrument accuracy is 0.5°C (Walker *et al.*, 1987), though experience indicates that the error can be larger than this at subzero temperatures.

The procedure to create the consolidate time series was as follows:

A) Compiling spatial average temperature series at four-hour intervals over a Unit Area/depth range.

1. Existing Data Reports (Gregory and Dobson, 1978; Dobson, 1979; Dobson, *et al.*, 1981a, b, c; 1982; 1983 a, b; 1984 a, b; 1985 a, b; Walker *et al.* 1986; 1987) were used to identify those stations/depth ranges, from the total of approximately 200, which repeatedly produce disparate records, apparently due to strong, localized effects. Corresponding plots of neighbouring records from the Data Reports were compared and scrutinized. Those stations which were discarded for our present climatological purposes are noted in Table 1.

2. To facilitate data handling for this project, all of the data were transferred to one tape, LC0496. A procedure was run that produced a database of header information about each partition (file) on Tape LC0496. This consisted of name, Unit Area, position, date and time, depth and the number of the partition on the tape. This data base was then split into two parts – deep and shallow. The deep and shallow databases were then sorted on the primary key of Unit Area code, and secondary keys of name, date and time, and depth. Data that were rejected for reasons given above were deleted. The resulting deep (shallow) database contained 502 (813) instrument records (Appendix A). A common starting date for all records was taken as January 1, 1967, to include one exceptionally long record from Unit Area 3La and to align all data series for later analysis.

A single data file was created for every Unit Area in the databases using the following procedure. The data, which may exist in a number of different files, for each separately named location in each Unit Area were fitted into one 'channel' in a single file, resulting in a gapped time series over the total 21-year (1967–1987) period of analysis. All channels for the Unit Area/depth range were then aligned in time, producing a single multi-channel file of four-hour data for each Unit Area. These files are named according to the scheme, zMuuuu where z indicates the depth range, deep (D) or shallow (S), M signifies merged, and uuuu is the Unit Area code. For example, SM3La represents shallow, merged, UNIT AREA 3La.

In order to prepare plots of the average (across all channels) for each Unit Area/depth range, a program was written to average simultaneous data across the channels, and write a file consisting of two channels — one containing the average of all input channels at 4-hour intervals and the second, the number of channels included in the average. These files are named zAuuuu, e.g., SA3La contains the 4-hourly averages for Unit Area 3La, upper depth range.

3. Computer-plots for each of these Unit Area/depth range series (at 4-hour sampling interval) are given in Appendix B. A second trace is also plotted, the number of locations incorporated in the spatial average. In a very few cases, where many records from many instruments were available, the number of data channels was reduced to satisfy system limits by first averaging data from instruments within a particular cove or bay. Then the 'tally' channel provides a lower bound on the number of instruments averaged at any time. In the majority of cases the 'tally' channel indicates the actual number of instruments included in a spatial average.

These plots sometimes revealed errors in the archived data which were instrumental rather than site-related. These portions of data were also excluded. One error which was encountered more than once was excessively low (below freezing) water temperatures. Table 2 identifies records for which portions were deleted for these instrument-related reasons.

B. Temporally- and Spatially-Averaged Series

1. Monthly Averaging

Monthly averages were formed from Unit Area/depth range, 4 h time series. Averages were computed for all months in the period January, 1967 to December, 1987, subject to the condition that at least 120 4-hourly samples were available i.e. at least twenty full data days.

2. Monthly Anomalies

A second time-series of monthly anomalies was created for each Unit Area/depth range. The monthly anomalies are calculated as the difference between the average temperature for the particular month and the grand mean of all 4-hour observations from all years for the month/Unit Area/depth range.

Table 3 shows the number of months for which anomalies could be calculated, the maximum and minimum anomalies found, the mean anomaly, and the standard deviation of anomalies. For some locations (e.g. D4Tg) there were a number of partial records (less than 120 4h samples, see B1 above) which contributed to the overall monthly mean but which were too short to form a monthly anomaly. This can lead to cases where the mean anomaly is nonzero.

Each monthly anomaly receives equal weight in the calculation of the mean anomaly; each four-hourly observation receives equal weight in the calculation of the grand mean from which the monthly anomalies are calculated.

Plots are shown (Appendix C) for each of the Unit Area/depth range of the monthly average series, the monthly standard deviations, the monthly time series and the monthly anomaly series. A description of the LTTMP data products archived on magnetic tape is given in Appendix D.

3. Data Coverage

An indication of the data coverage can be obtained from Figures 2 to 5. Figures 2 and 3 show the number of February monthly averages available in upper and lower depth ranges respectively. Figures 4 and 5 show the number of August monthly averages available.

Analyses

A. Patterns of Variance

An example of the statistics that have been computed for the Unit Areas is given in Table 4 for S3La, one of the most sampled Unit Areas. The monthly means and total standard deviation from Table 4 are plotted in Appendix C; the total standard deviations as well as contributions due to within-month variance and between-monthly means are plotted in Figure 6. The within-month standard deviation (W) is made up of a contribution from high frequency oscillations and the low frequency, temperature trend (\hat{t} , see Fig. 6) during the month. The between-monthly means contribution (B) reflects interannual variability, i.e., the variance of the monthly means. The square of the total standard deviation (T) is the sum of the squares of the standard deviations within the month and of the monthly means.

The grand mean for January (Table 4), derived from 2,337 readings (at 4-hour intervals) during January in eight different years, is -0.27°C . The total standard deviation is 1.18°C .

The total standard deviation for January (Table 4) has a greater contribution from the set of monthly means (0.89°C) than from the within month component (0.77°C). Generally, though, the standard deviations of the monthly means are less than the within month standard deviation. The average ratio of these two

quantities (Table 4) for area S3La is 0.84. In August, for example, the interannual standard deviation of August means is 0.89°C , while the standard deviation within the month is 1.82°C .

Scanning the seasonal cycle for S3La, February and March grand mean temperatures (Table 4) are near the freezing point while the maximum monthly average is reached in August. The seasonal cycle of the trend contribution to within-month standard deviation (Table 4 and Figure 6) has peaks in the warming and cooling periods. The seasonal cycle of interannual, between-monthly-means standard deviation, is again high in spring but low in October and November although high in December. The total standard deviation is highest during the warming season and peaks again late in the year. This pattern is repeated in many Unit Areas.

The above results (Table 4 and Figure 6) do show, for Unit Area S3La, that ambient temperature variability from each of the within-month and between-monthly-means contributions is generally on the order of 1°C . This is larger than the instrumental uncertainty of 0.5°C and therefore likely real. However, successive gauges reading, respectively 0.5°C above and below the true temperature can give rise to low frequency variance of 0.25°C^2 , i.e., a standard deviation of 0.5°C .

B. Comparison of Unit Area/depth range monthly averages with ship-of-opportunity monthly averages for contiguous areas.

February

The February grand mean temperatures in the nearshore Unit Areas/upper depth range (Figure 7) are lowest in the Gulf of St. Lawrence, the eastern coast of Newfoundland and the Eastern Shore of Nova Scotia. The warmest nearsurface temperatures are found in the Bay of Fundy and Southwest Nova Scotia region. Comparison with the 1946–80 average February sea-surface temperatures from ship-of-opportunity observations (Loucks *et al.*, 1986) shows that the coastal temperatures are generally lower. This could arise from the different time periods covered by the two data sets or because these shallow, nearshore sites are the first marine areas exposed to the cold, continental winds resulting in large heat losses (Thompson *et al.*, 1988). The ship-of-opportunity areas include offshore regions where air-sea differences in temperature have more-nearly equilibrated.

On the other hand, the LTTMP results compare favourably with the long term average sea surface temperatures (SST) at coastal sites. Comparing the coastal monthly means to the ones in Fig. 7, we have for St. Andrews 1.0°C (SST) versus 0.1°C (LTTMP), Halifax 1.2°C and -0.6°C (average of 0.7 and -1.9°C), Entry Island -1.3 and -1.8 , and St. John's -0.7 and -0.3 .

Lower depth range February grand mean temperatures in the nearshore Unit Areas, though not available for as many areas as for the upper depth range, show a similar pattern (Figure 8).

August

The August mean temperatures from the shallow layer, nearshore gauges compare very well with the long term average sea surface temperatures from coastal sites. For St. Andrews we have 13.3°C (SST) compared to 14.2°C (LTTMP, Figure 9), at Halifax 14.9°C versus 13.9°C , at Entry Island 17.3°C and 17.5°C , at Port Borden 18.8°C and 17.7°C and at St. John's 13.0°C and 13.0°C . Nearshore temperatures in those Unit Areas which are southeast-facing are lower than in the larger, shelf-wide ship-of-opportunity areas (Loucks *et al.*, 1986) perhaps suggesting wind-driven coastal upwelling. Lower temperatures on the north shore of the Gulf of St. Lawrence also suggests the inflow of Labrador Shelf water through the Strait of Belle Isle.

Generally the lower depth range averages (Figure 10) show a pattern related to the upper depth range pattern modified by the stratification. Lower range averages are not directly comparable with ship-of-opportunity, surface averages. Unit Area 3KI actually exhibits a higher August average temperature in the lower than in the upper depth range! However, the upper layer estimate is based upon six August means

and almost 3000 data points, whereas the lower range average incorporates only one August and 183 data points. Thus, this inversion is probably a result of the difference in data availability.

C. Space scales of correlation within and between Unit Areas

The correlation matrix was calculated between all Unit Area/depth range monthly anomaly series. All correlations that have been computed between any two time series are based only on those months with contemporaneous anomalies. The full matrix may be obtained from D. Gregory, Physical and Chemical Sciences Branch, Department of Fisheries and Oceans, Dartmouth, Nova Scotia.

Significant low frequency variability at time scales of several years is apparent for the longest anomaly data series from the shallow depth in area 3La (Appendix C). This implies that even monthly anomalies may not be independent of one another and that the number of degrees of freedom is far fewer than the number of monthly averages. Petrie *et al.* (1990) estimated that this series of 117 monthly averages had only six degrees of freedom. Accurate estimation of the number of degrees of freedom for all other series is unlikely since they have fewer observations on which to base the calculation. Consequently, we expect that few of the correlations are significant at the 95% level. Though the significance of individual correlations may be in doubt, plotting all of the correlations possible from a broad area, such as the Newfoundland coast or the Gulf of St. Lawrence, as a function of separation may reveal a consistent pattern.

1. Correlations between shallow and deep time series within unit areas

Correlations have been calculated for the 23 shallow and deep time series which had sufficient contemporaneous data. The results are presented in Table 5 for the unit areas by region. Overall, the average absolute value of the correlation coefficient is 0.40 and the average number of data months, 26.5. Eight of the 23 correlations were significant at the 95% level if all of the monthly anomalies were assumed to be independent samples. Four of these 8 were from the Gulf of St. Lawrence. Eight of the 23 correlations were negative, 5 of these were from the Gulf of St. Lawrence along the mainland shore of the Magdalen Shallows from the Baie de Chaleur to Cape Breton, with a sixth negative value in Sydney Bight.

2. Correlations between unit areas by region

Correlations were calculated for time series between unit areas from the same depth layer (shallow and deep), and by region. The four regions were Newfoundland, the Gulf of St. Lawrence, Scotian Shelf and the Bay of Fundy. The correlation matrices for both layers are shown in Tables 6–9 and are plotted as a function of separation in Figures 11 – 14.

Several ways of attributing a length scale to the correlation functions were examined. Two forms will be considered in the following discussion: e^{-kx} , which describes a correlation function that is 1 for 0 km separation and goes to zero as x becomes large; and, $2e^{-kx}-1$, which is also 1 for 0 km separation but goes to -1 as x becomes large. The first form of the correlation function allows for in-phase variations over a region, while the second allows for in- and out of phase variations. In this respect, they correspond to modes 1 and 2 respectively of Thompson *et al.* (1988). The application of either or both of these will depend on the structure of the correlations as a function of separation.

a) Eastern and Southern Newfoundland

Shallow anomalies The average data span for the 44 correlations shown in Table 6a was 24 months. Twenty of 21 correlations for the east coast regions, 3Kd to 3Lj have positive correlation coefficients. Twelve of the 14 negative correlation coefficients are between south coast areas 3Lq and 3PSb and east coast areas. It appears then that along the east coast, temperature anomalies are positively correlated but are negatively correlated with the anomalies observed along the south coast. The exception is area 3PSc on the south coast which behaves as if it were an east coast station.

The structure of the correlations as a function of separation (Fig. 11) shows that as separation increases correlations decrease. The function $2e^{-kx}-1$ (Fig. 11) does a reasonable

job of fitting the data qualitatively. The standard deviation of the observed correlations from this line is 0.44, a value that the function reaches at distances of 200 km. Petrie *et al.* (1990) found a correlation of 0.43 for the 117 month T time series from Stock Cove (9 m) and Sta. 27 (0-20 m average) which are separated by 170 km on the east coast of Newfoundland. The function shown in Figure 11 gives 0.52 for the same separation, in good agreement. We have also fitted the function e^{-kx} to the 20 positive correlations for the east coast and find that $k=0.00321 \text{ km}^{-1}$, corresponding to an e-folding scale of about 300 km.

Deep anomalies. The average data span for the 14 deep correlations is 8 months, considerably less than for the shallow layer observations. Moreover, there does not appear to be any dominant structure to the correlations (Table 6b, Fig. 11) as there was with the shallow correlation matrix. The least squares fit of $2e^{-kx}-1$ (Fig. 11, Table 10) does not model the observations very well. The correlations appear to be randomly distributed about 0 even at small distances.

b) Gulf of St. Lawrence

Shallow anomalies There are two areas of the Gulf, the Northeastern Gulf and the Magdalen Shallows, where there are sufficient data to examine the correlations more closely. The areas in the Northeastern Gulf, 4Rc, 4Rb and 4Sw, are positively correlated at about the 0.7 level (Table 7a). The correlations for the Magdalen Shallows areas, 4Tm-4Tf, and the Sydney Bight, 4Vn, (average data length, 15 months; Table 7a, Fig. 12) appear to decrease with increasing distance. The standard deviation of observed correlations from the function $2e^{-kx}-1$ (Fig. 12) is 0.36 (Table 10). The function has this value at 210 km.

Deep anomalies The average data span for the deep time series from the Shallows is only 8 months. Moreover, the correlations appear to be randomly distributed about zero (Fig. 12) for separations of from approximately 100 to 400 km. The functional fit (Fig. 12, Table 10) does not do a good job of fitting the correlations, which have a standard deviation from it of about 0.6. The spatial variability of the long period temperature anomalies are probably less than station separations.

c) Nova Scotia Atlantic Coast

Shallow anomalies The average data span for the 5 areas of the Atlantic coast of Nova Scotia is 26 months. The correlations (Table 8, Fig. 13) are all positive. Though the function $2e^{-kx}-1$ does a good job of fitting the data (Fig. 13, Table 10) with a residual standard deviation of 0.21, the function e^{-kx} does better, with a residual standard deviation of 0.14. The e-folding scale of the latter is 210 km.

Deep anomalies. On the other hand, the deeper layer correlations (Table 8, Fig. 13) have a mixture of positive and negative values apparently randomly scattered about zero. The spatial scale of these correlations, calculated from a data series of 21 months average duration, is probably smaller than the minimum separation of stations.

d) SW Nova Scotia — Bay of Fundy

Shallow anomalies These records have the shortest average data span, 7 months, of all the areas discussed. Moreover, the correlations (Table 9, Fig. 14) are too few and scattered for us to have confidence in their behaviour as a function of separation. The functional fit (Fig. 14, Table 10) is the poorest of all areas.

Deep anomalies The situation for the deep anomalies is much the same as for the shallow ones. The average length of the time series is 16 months, more than twice the length of the shallow series. However, the structure of the correlations (Table 9, Fig. 14) and the least squares fit are only marginally better.

Summary It appears that the spatial scales of T anomalies are greater than the minimum separations between stations only for the shallow observations from the eastern Newfoundland coast, the Northeastern Gulf of St. Lawrence, the Magdalen Shallows and the Atlantic coast of Nova Scotia. For none of these cases is a scale greater than about 200–300 km indicated. Correlations appeared to be randomly distributed about zero for the deeper levels in all regions. This may be due in part to gauges at these depth levels being

in the thermocline more frequently and thus subject to more data noise in the form of high frequency variability. There is some support for this as the overall ratio of temperature variance at the deeper level to that at the shallow level is 1.10. The ratio varies from a low of 0.81 in April from a total of 7 areas to 1.41 in September from a total of 27 areas.

D. Correlations with other time series.

In the Gulf of Saint Lawrence, shallow and deep temperature correlations with RIVSUM, were calculated. RIVSUM is the time series of composite discharge into the Gulf of Saint Lawrence. The average correlation of the 13 shallow series (average duration, 12 months) with RIVSUM was -0.03 (s.d. 0.36); for the 11 deep series (average duration, 12 months), the average correlation was -0.06 (s.d. = 0.34). The maximum (minimum) correlation was with the time series of area S4Tp (D4Sy) with a value of 0.66 (-0.62). Correlations of the deep and shallow time series from areas 4Xr, 4Xq and 4Xo with St. Andrew's sea surface T were also disappointing. The average correlation was 0.18 (s.d.=0.28) for a time series of average duration of 37 months.

Conclusions

A. Instrument Performance

There is concern that the thermographs may perform poorly at low temperatures. This difficulty becomes apparent in cases where temperatures below the freezing point of seawater are recorded.

B. Data Coverage

The data coverage, especially in winter, seems sparse. Winter temperatures are particularly significant for the survival of farmed fish and, at least on the open shelf (Thompson *et al.*, 1988), for predicting temperature regimes in subsequent seasons.

C. Climatic Averages

The Unit Area/depth range monthly grand averages correspond reasonably closely with long-term monthly averages from contiguous ship-of-opportunity areas (Loucks and Trites, 1985; Loucks *et al.*, 1986).

D. Space Scales

Our analyses suggest that establishing statistically significant correlations for one unit area versus another may require very long time series as the data appear to be strongly autocorrelated. However, for the eastern coast of Newfoundland, Nova Scotia and for the Magdalen Shallows and Northeastern Gulf of St. Lawrence, the distributions of correlations for the shallow depths have definite patterns. The correlations are generally positive at small separations and decrease with increasing distance. However useful correlations at about the 0.7 level will likely only be attained for separations less than 100 km. This scale is considerably smaller than the scale of order 1000 km found by Thompson *et al.* (1988). We do not think that this is due primarily to the shorter time series which we have analyzed. Rather a more likely conclusion is that spatial scales of variability are indeed smaller at the coast due to geography than they are in the open shelf areas considered by Thompson *et al.* This implies that some applications, e.g. aquaculture operations, may have to be dealt with on a site specific basis.

E. Seasonal Pattern of Total Variance

A consistent seasonal pattern appears in the monthly total variances (and standard deviations). Total variances are small in winter, then rise to a peak in the warming season, subside during summer, and rise to a secondary peak during the cooling season. The warming/cooling trends during spring/autumn months enhance the total variance through the within-month variance and explain much, but not all, of the double-peak pattern in total variance. Interannual variance is evident in these series.

Recommendations

As part of this project, the consulting firms were asked to make recommendations, independent of DFO. These recommendations are given below:

A) An improved model thermograph which is accurate at low temperatures is available. It is recommended that it be considered for purchase to replace the Ryan recorders.

B) Winter records are especially valuable, both for the aquaculturalist, because of the possible occurrence of lethal temperatures, and for the marine climatologist, because of the importance of winter cooling in establishing climate through the following summer. It is recommended that a sampling design study be made to determine the cost/effectiveness of obtaining more winter records.

The objectives of the LTTMP may be shifting from obtaining baseline data to detecting extremes and long-term trends. Sampling-design could guide the future of the LTTMP by integrating the shifting objectives, the space scales estimated above, and the budget. Millard and Lettenmaier (1986) provide a framework for the appropriate sampling design.

C) An analysis of autocorrelation functions and patterns of (corrected) variance components could distinguish the contributions to total variance from seasonal trends, long-term trends, within-month variance and interannual variance. For example, are there geographic patterns in between-year variance due to variability in the onset of spring warming, as contrasted with strong, within-month variance due to differential heating? It is recommended that an analysis of autocorrelation and variance proceed and feed into sampling design.

D) It is recommended that space scales be further analyzed employing an empirical orthogonal function analysis analogous to the treatment carried out by Thompson *et al.* (1988).

E) It is recommended that, for the aquaculturalist, this data base be used to estimate the return period for various extreme temperature episodes, their magnitude and duration.

Table 10. Least squares fits of correlations (Fig. 11-14) as a function of separation by region by the expression $2e^{-kx} - 1$. The standard deviations (s.d.) of the calculated correlations are given as well as the distance at which the function equals the s.d.

Area		Number of Correlations	k(km⁻¹)	S.D.	Distance where fit = S.D. $L = -\ln((r+1)/2)/k$
Nfld	Shallow	44	.00163	0.44	200
	Deep	14	.00366	0.53	70
Gulf	Shallow	27	.00174	0.39	210
	Deep	24	.00294	0.59	80
Nova Scotia	Shallow	10	.00143	0.21	350
	Deep	9	.00216	0.44	150
Fundy	Shallow	5	.00297	0.65	60
	Deep	6	.00211	0.57	110

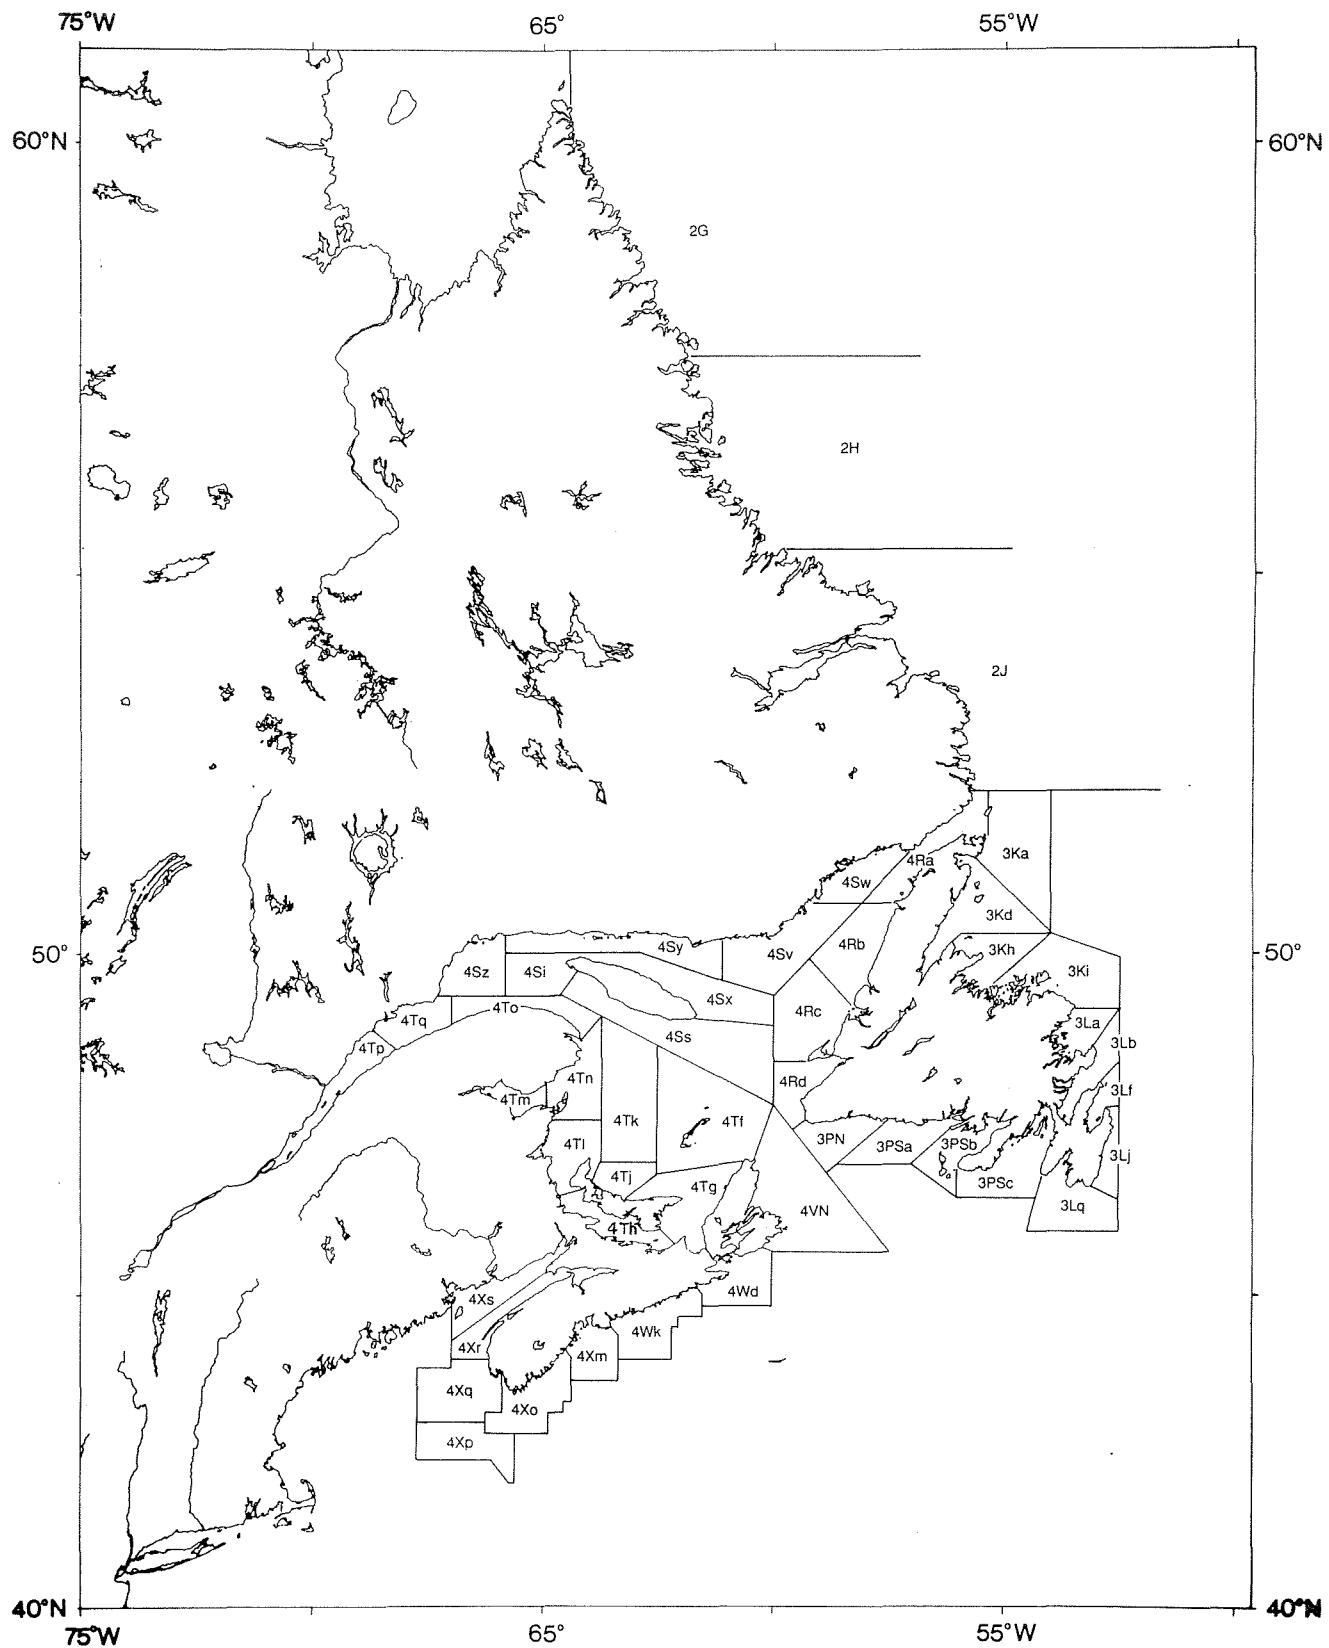

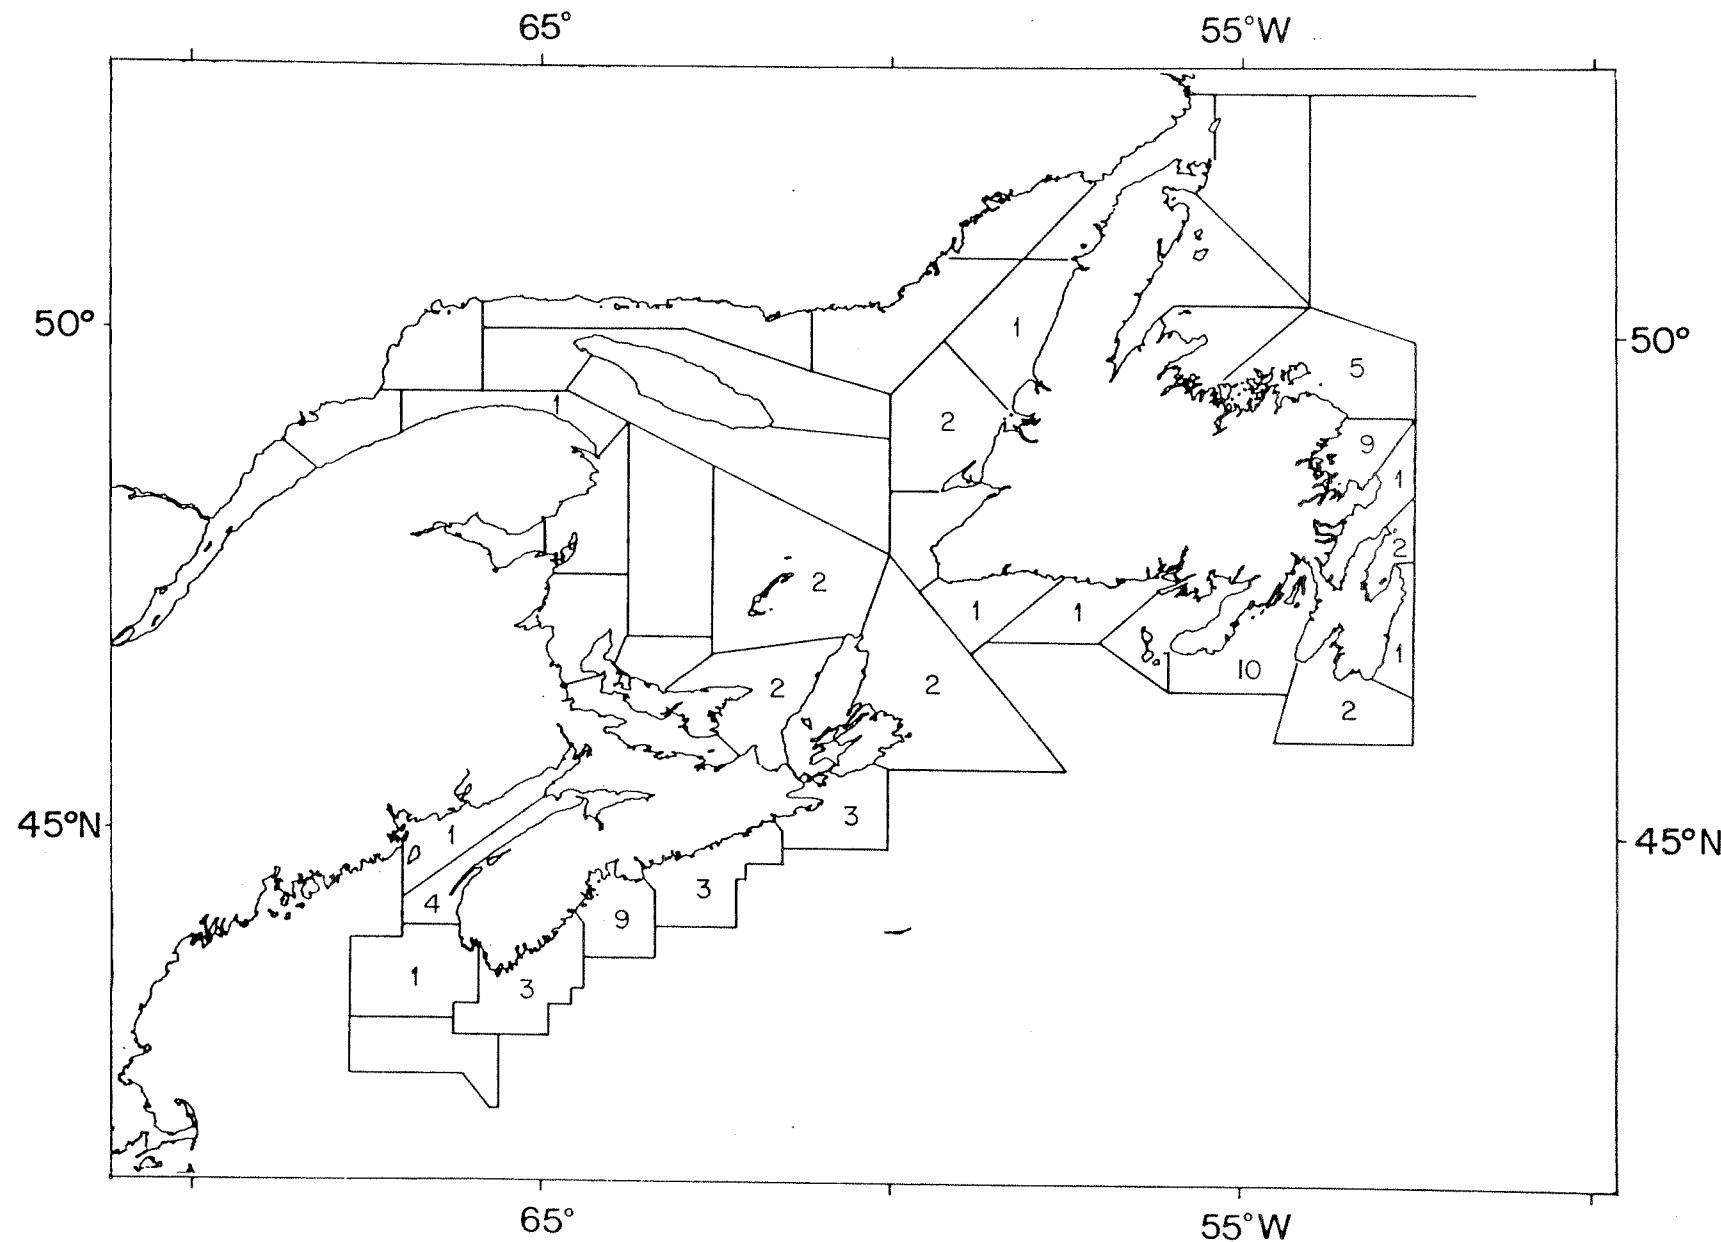

DEPARTMENT OF FISHERIES AND OCEANS
UNIT AREAS

Figure 1. Chart of Unit Areas

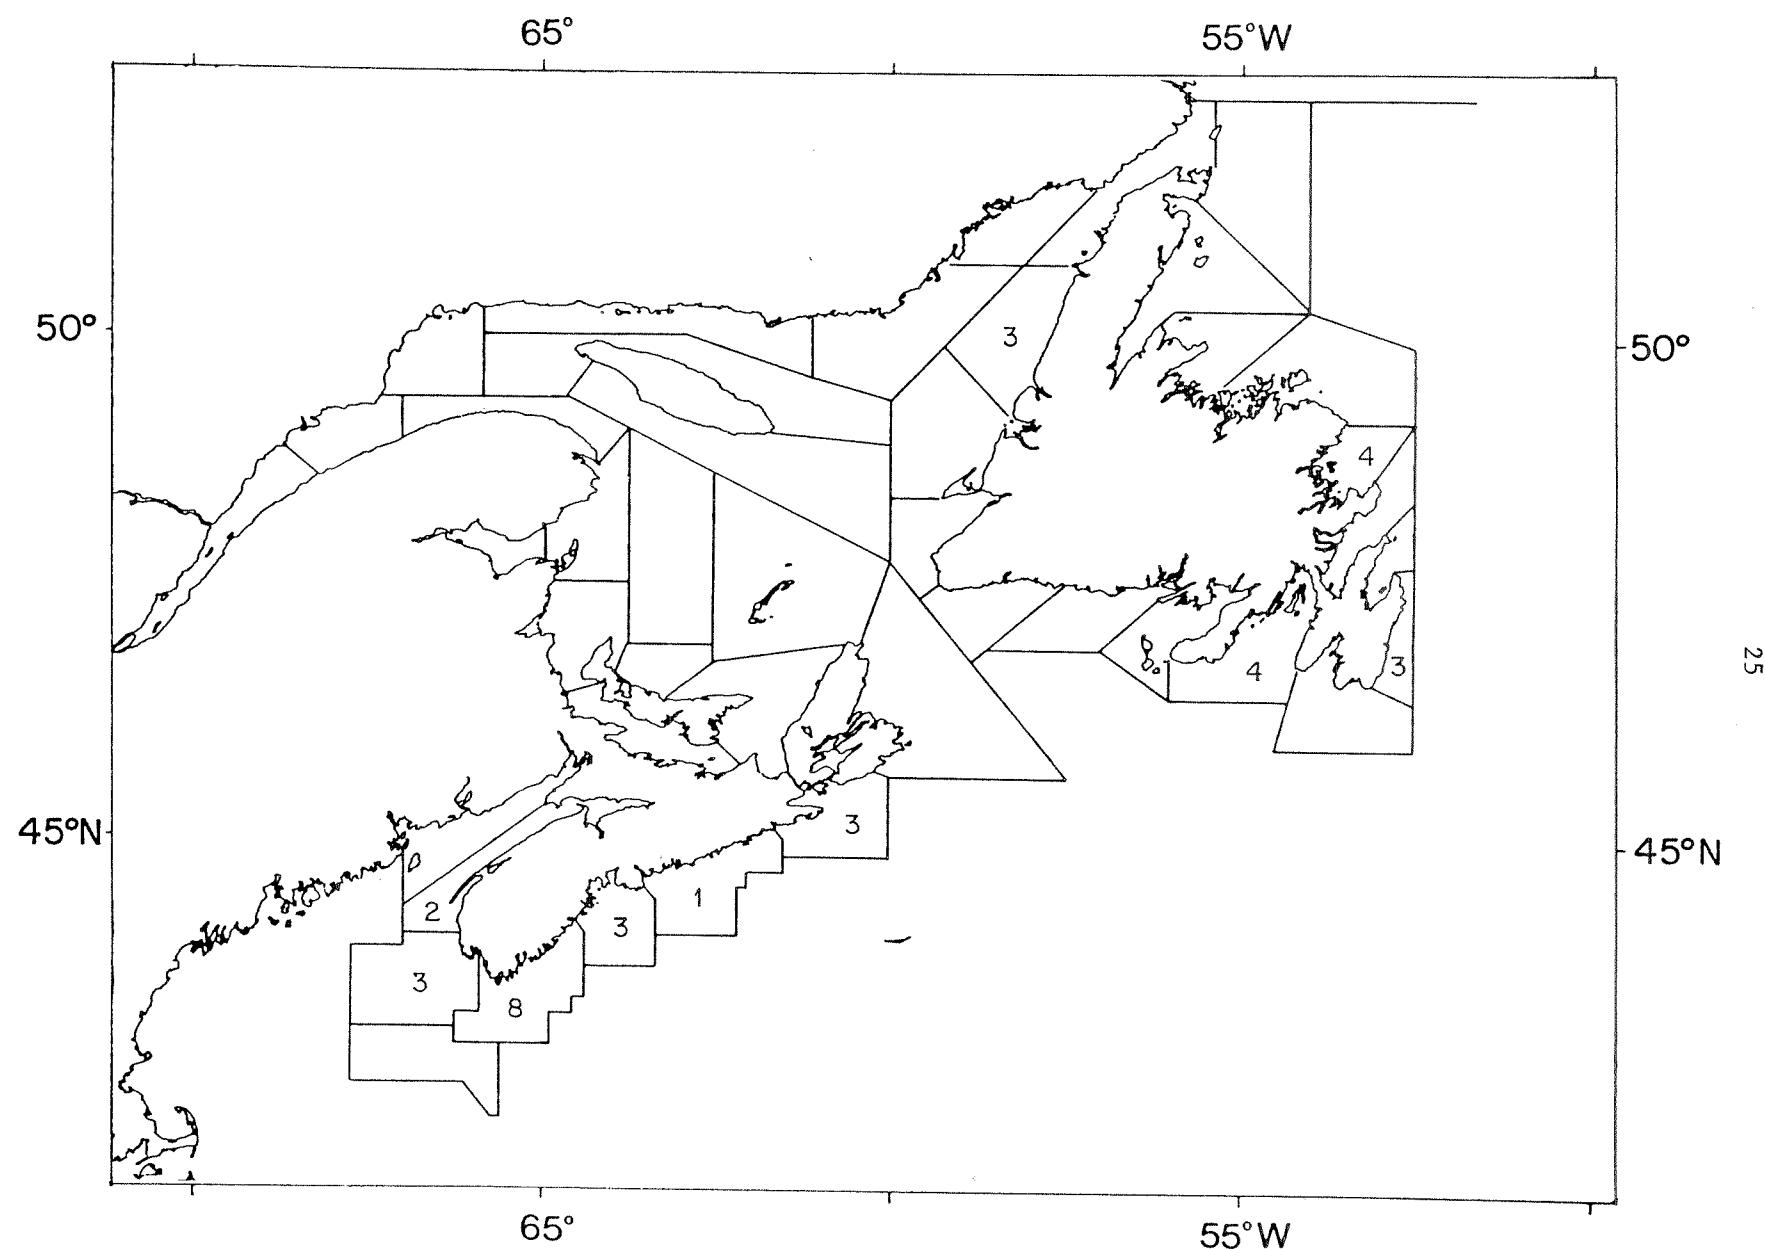

Figure 3. Chart showing available number of February monthly averages by Unit Area (lower depth range).
There are no monthly averages from areas 2G, H and J.

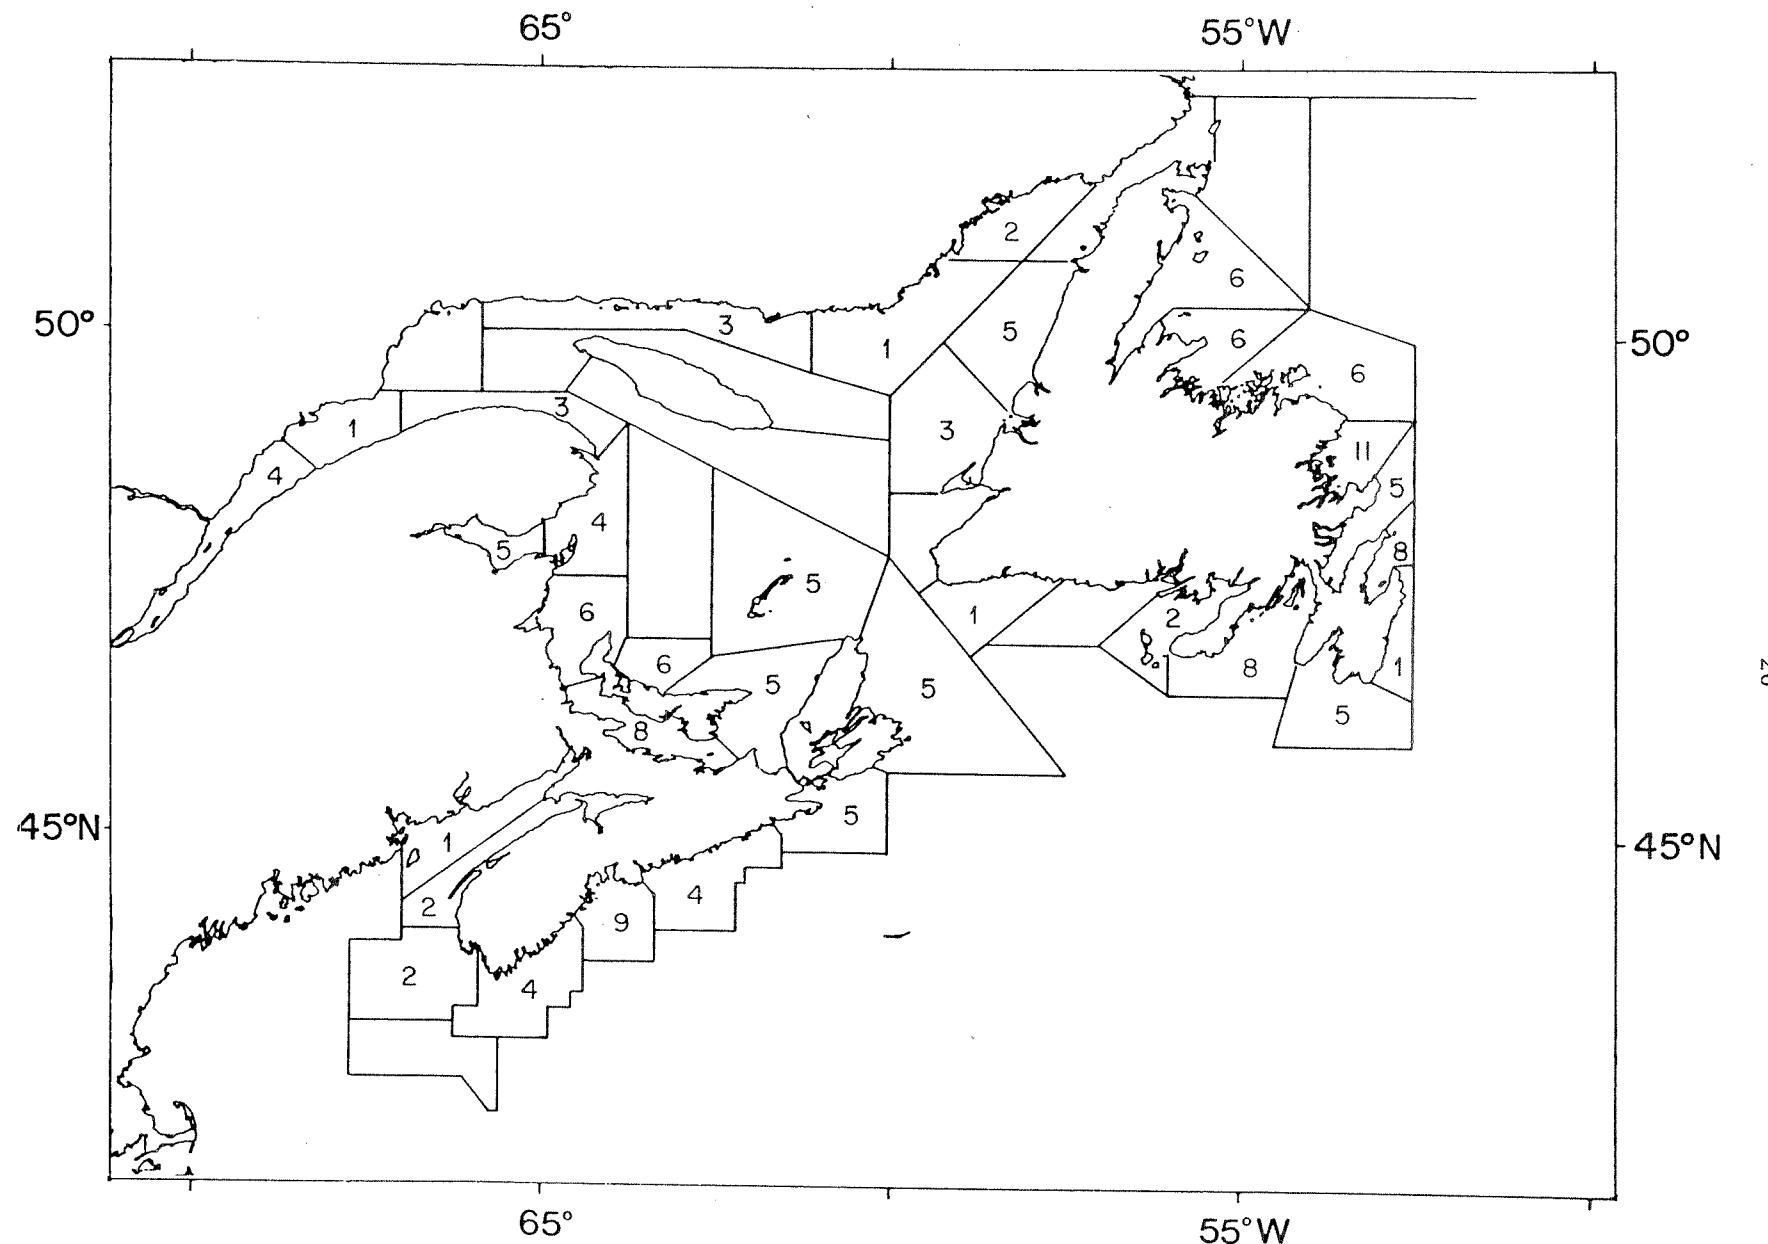

Figure 4. Chart showing available number of August monthly averages by Unit Area (upper depth range).
One monthly average is available from areas 2H and 2J.

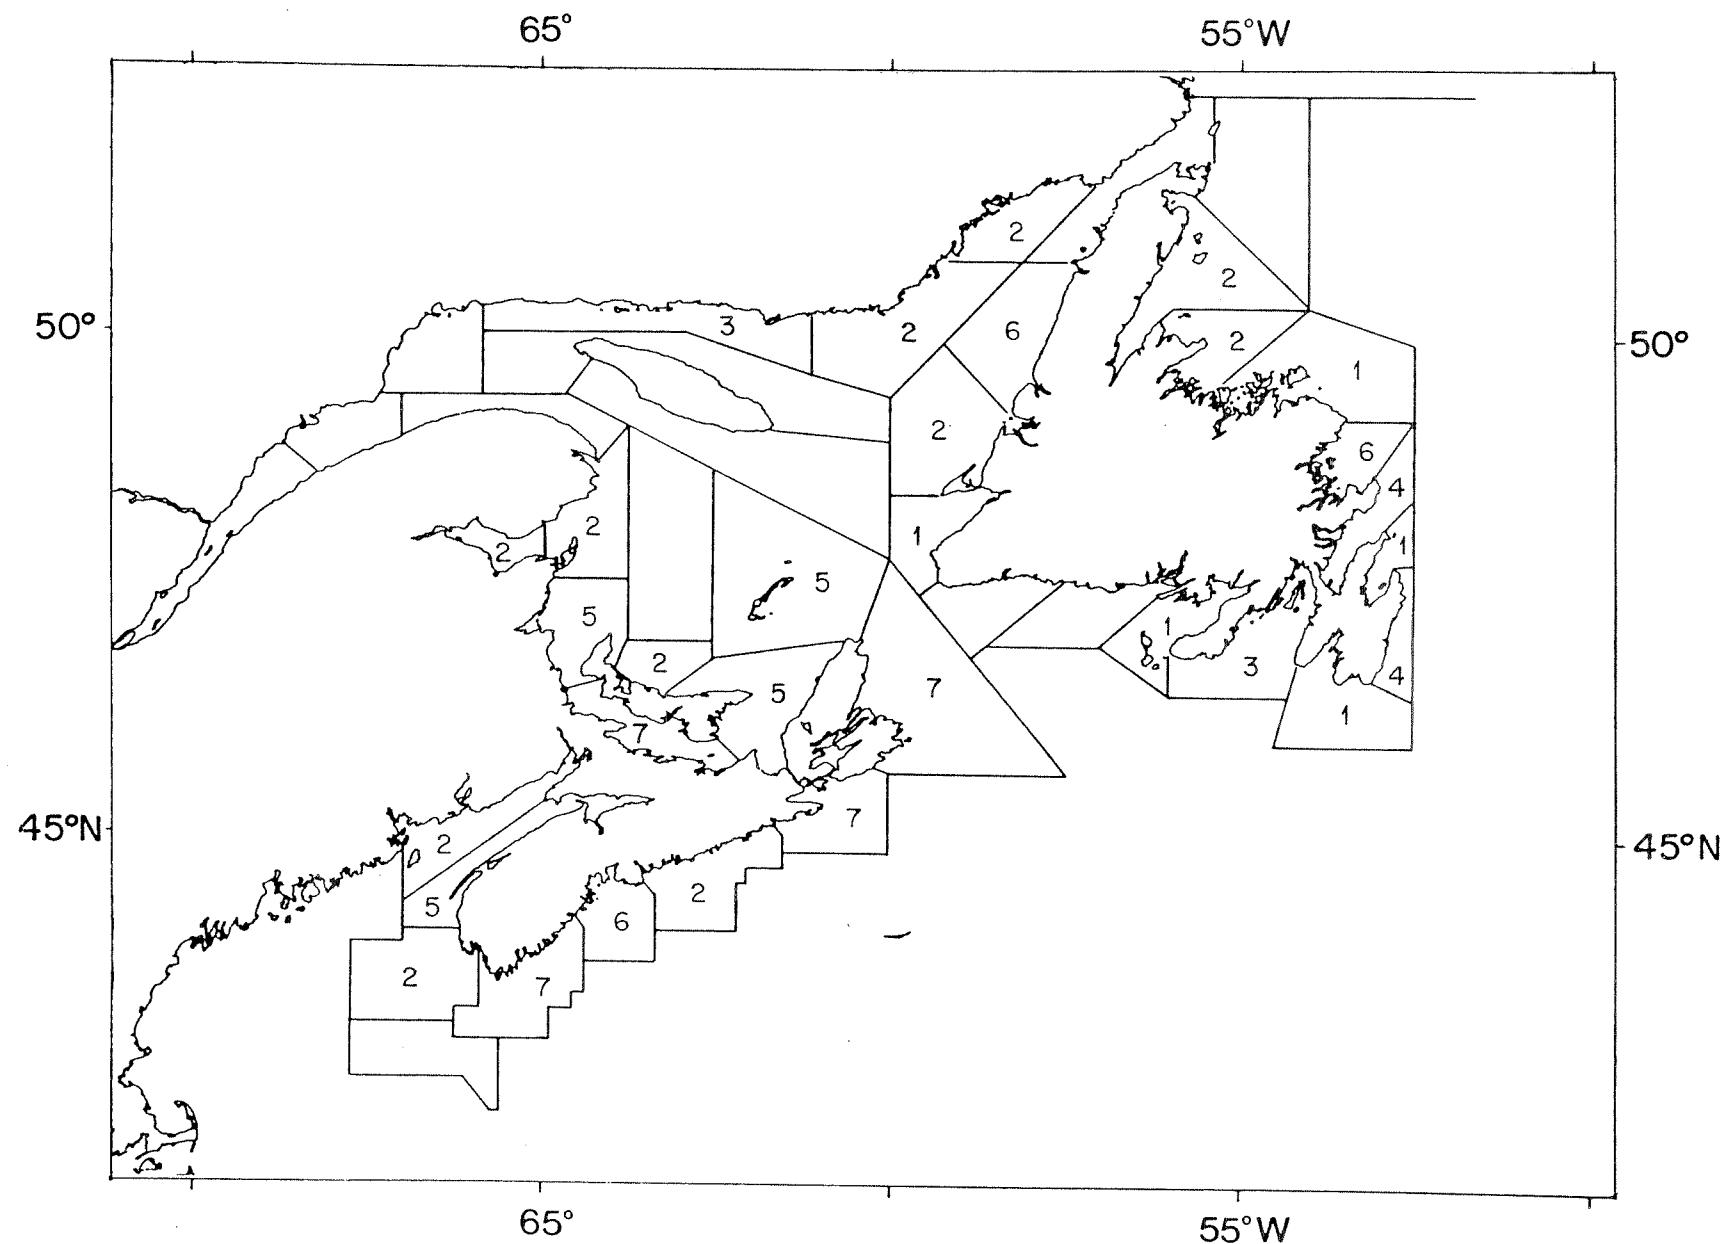

Figure 5. Chart showing available number of August monthly averages by Unit Area (lower depth range).
There are no monthly averages from areas 2G, H and J.

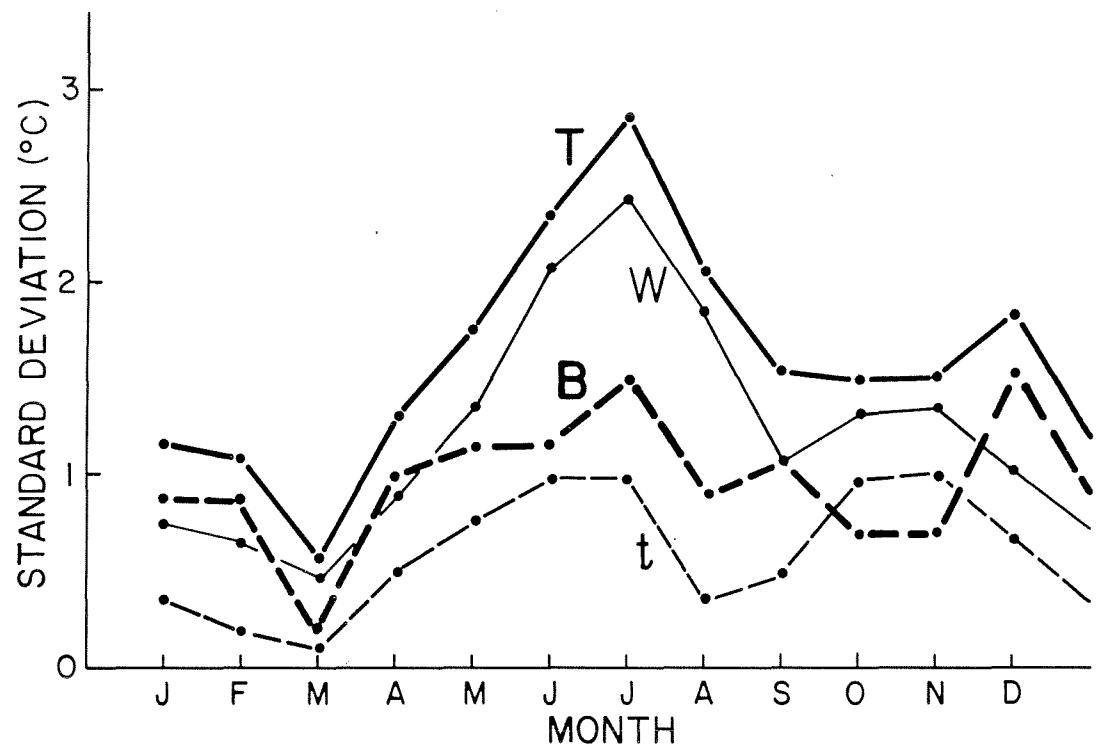

Figure 6. Seasonal cycle of components of standard deviation for the well-sampled Unit Area, S3La. The letter 't' identifies the contribution from seasonal trend; 'W', the within-month component; 'B', the interannual standard deviation of monthly means; and 'T', the total standard deviation.

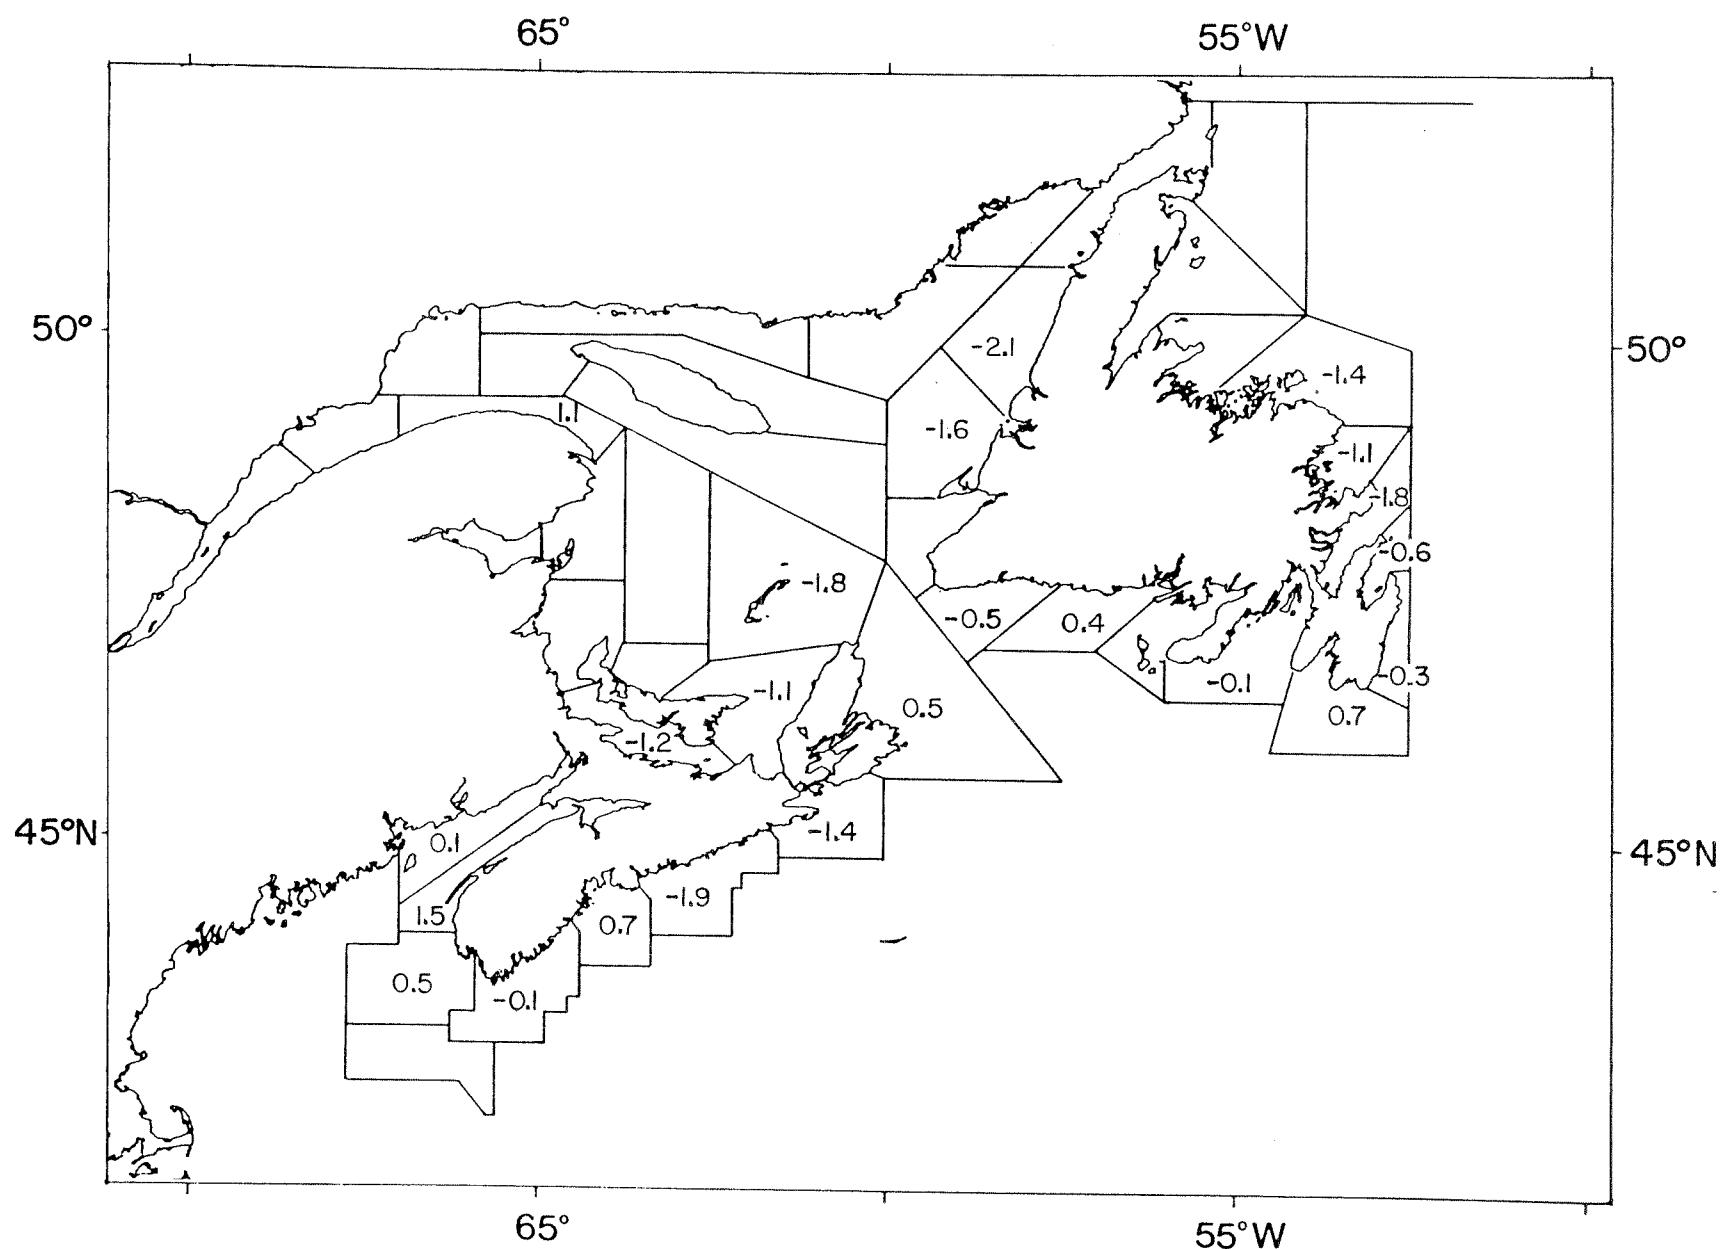

Figure 7. Chart showing grand mean February temperatures by Unit Area (upper depth range).

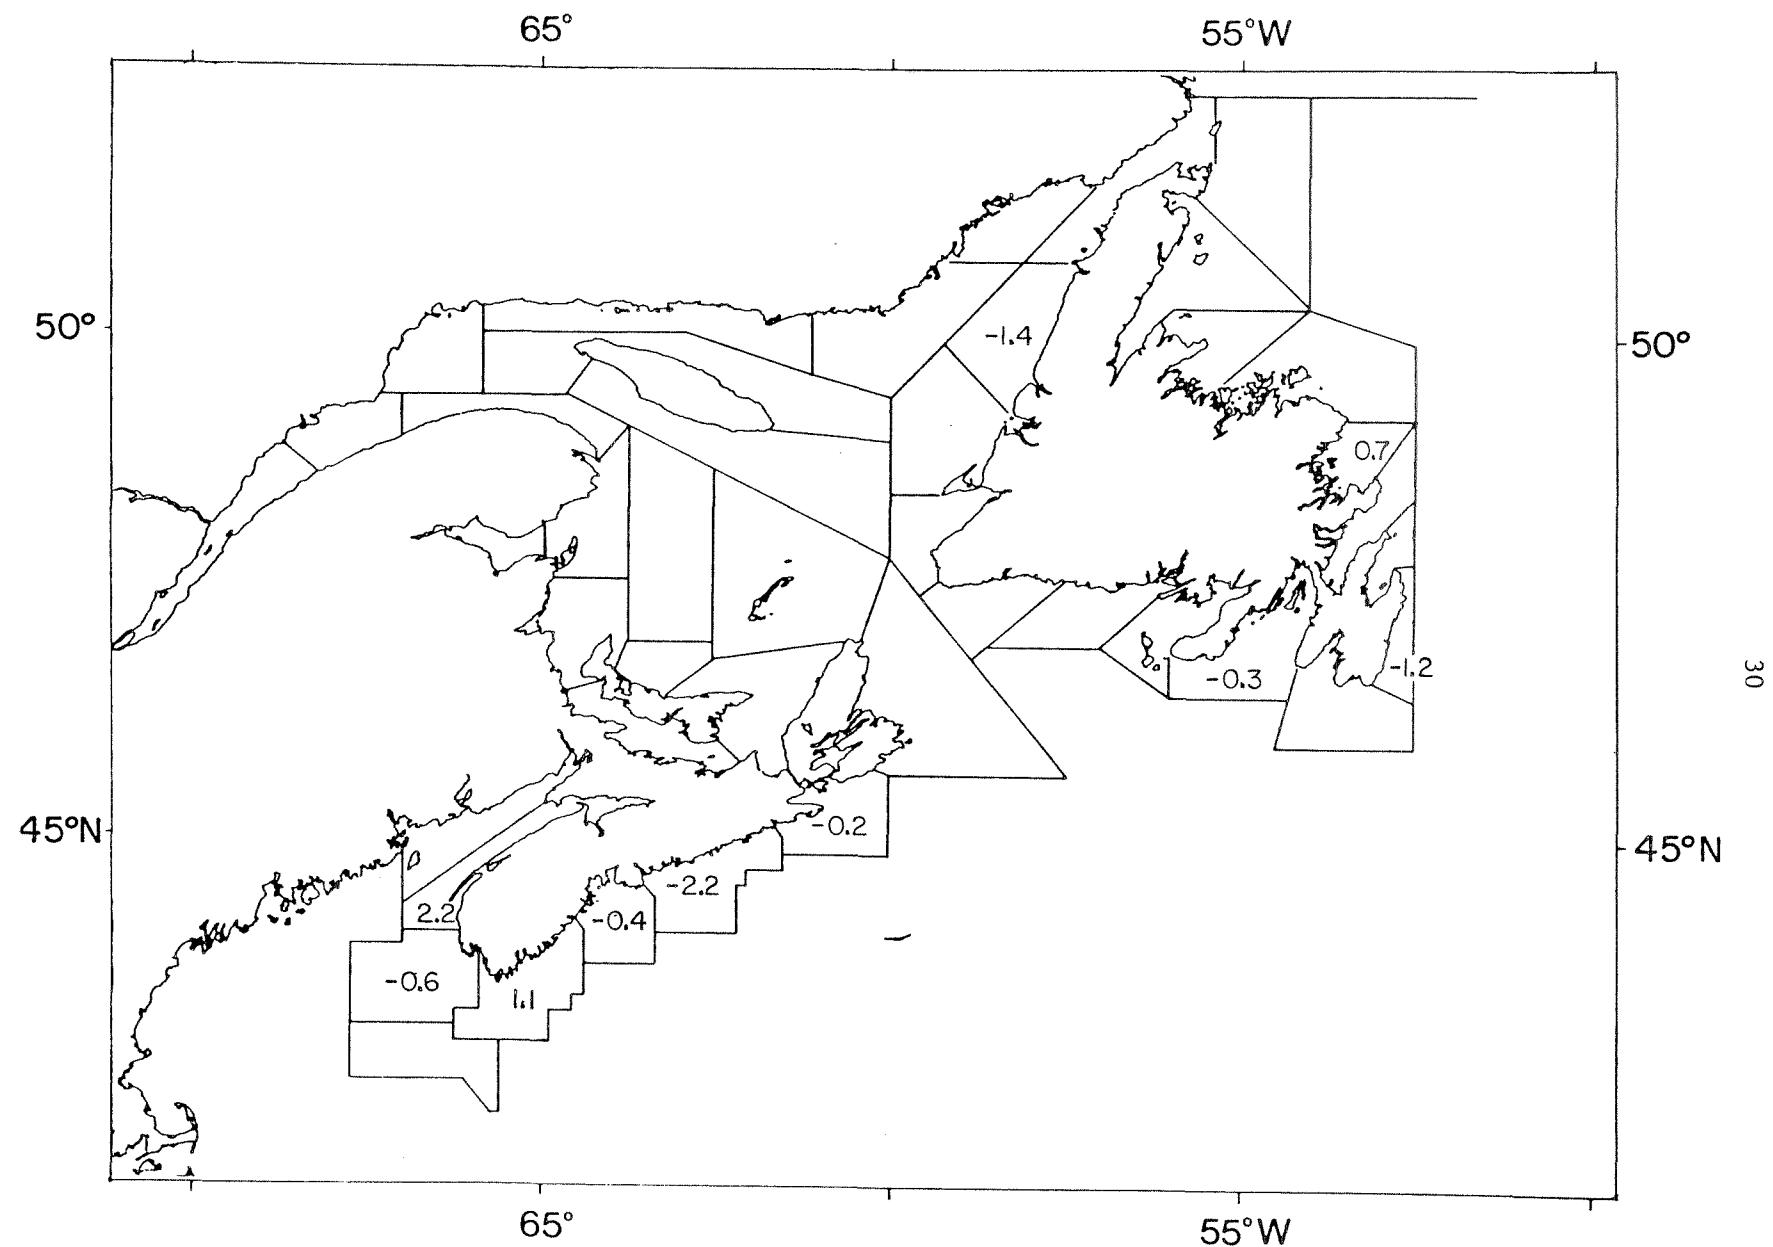

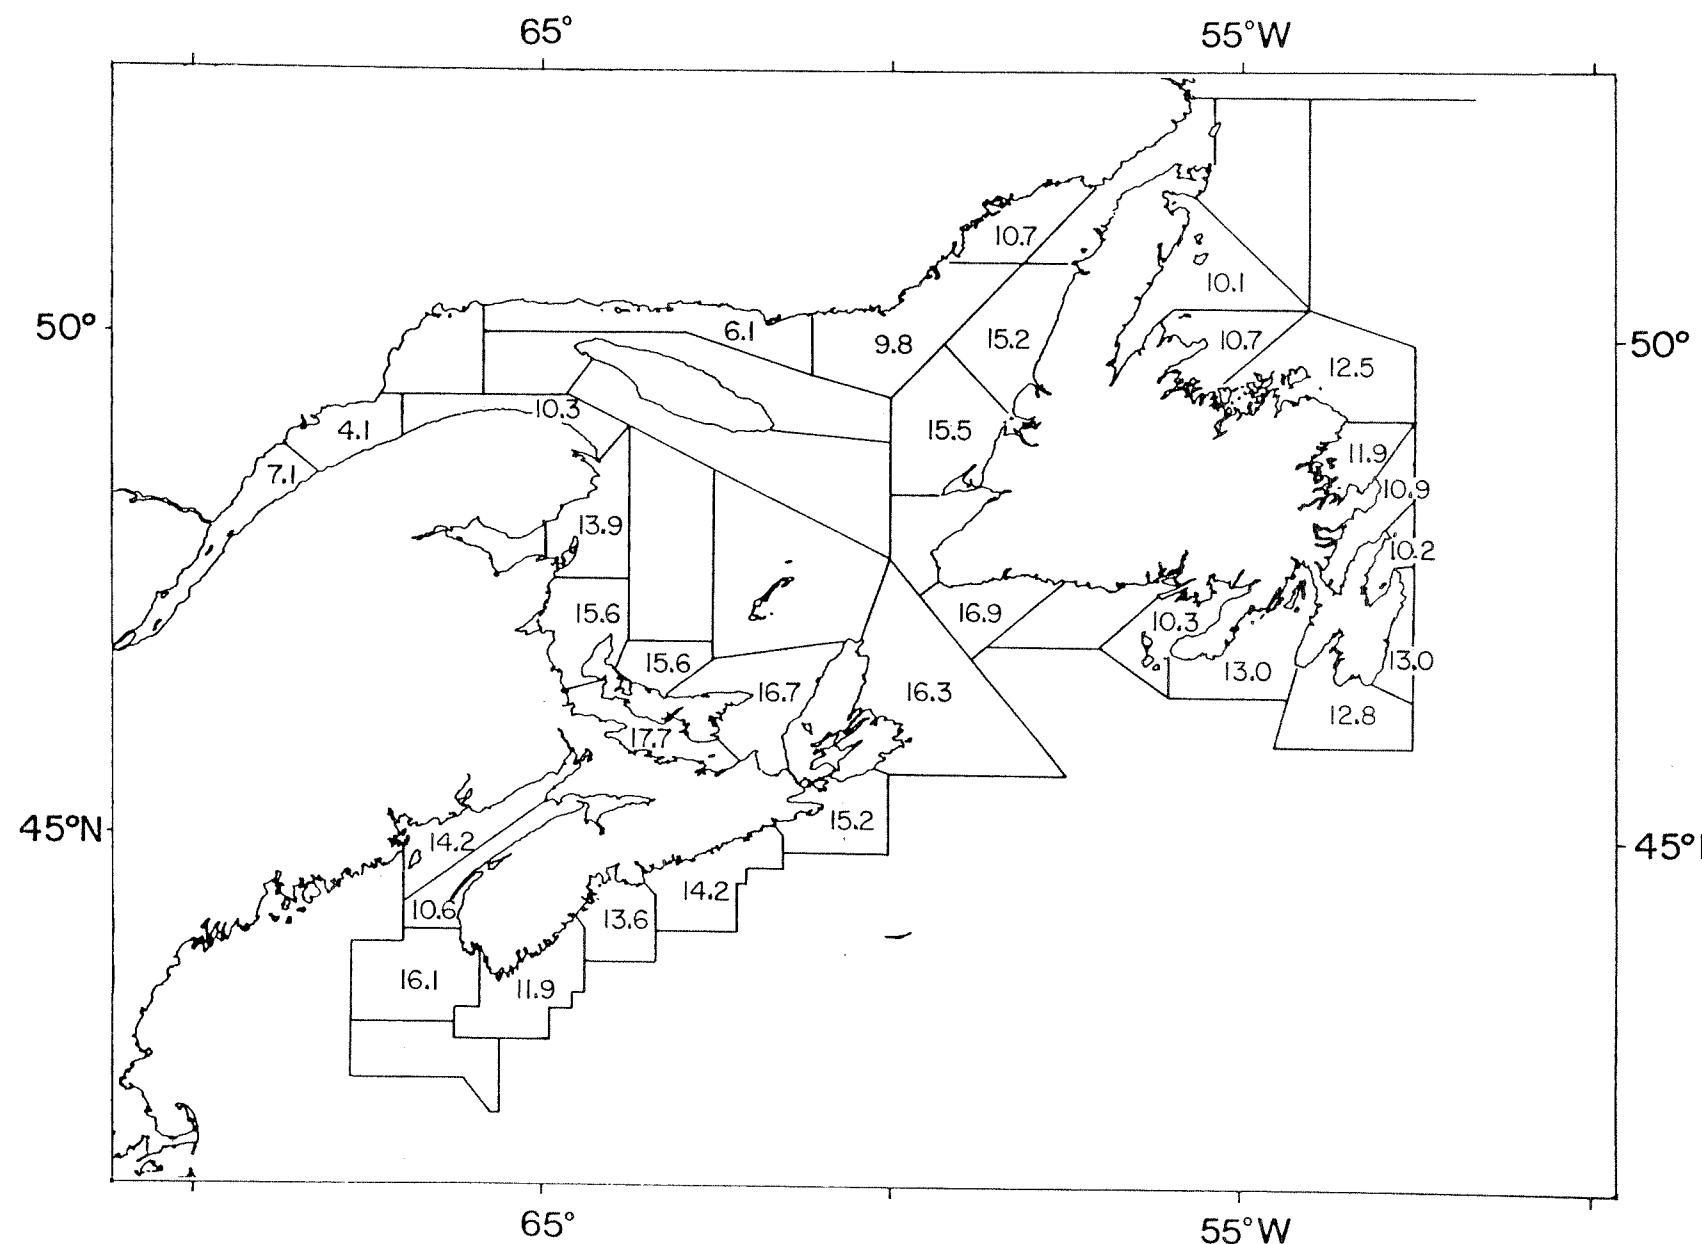

Figure 8. Chart showing grand mean February temperatures by Unit Area (lower depth range).

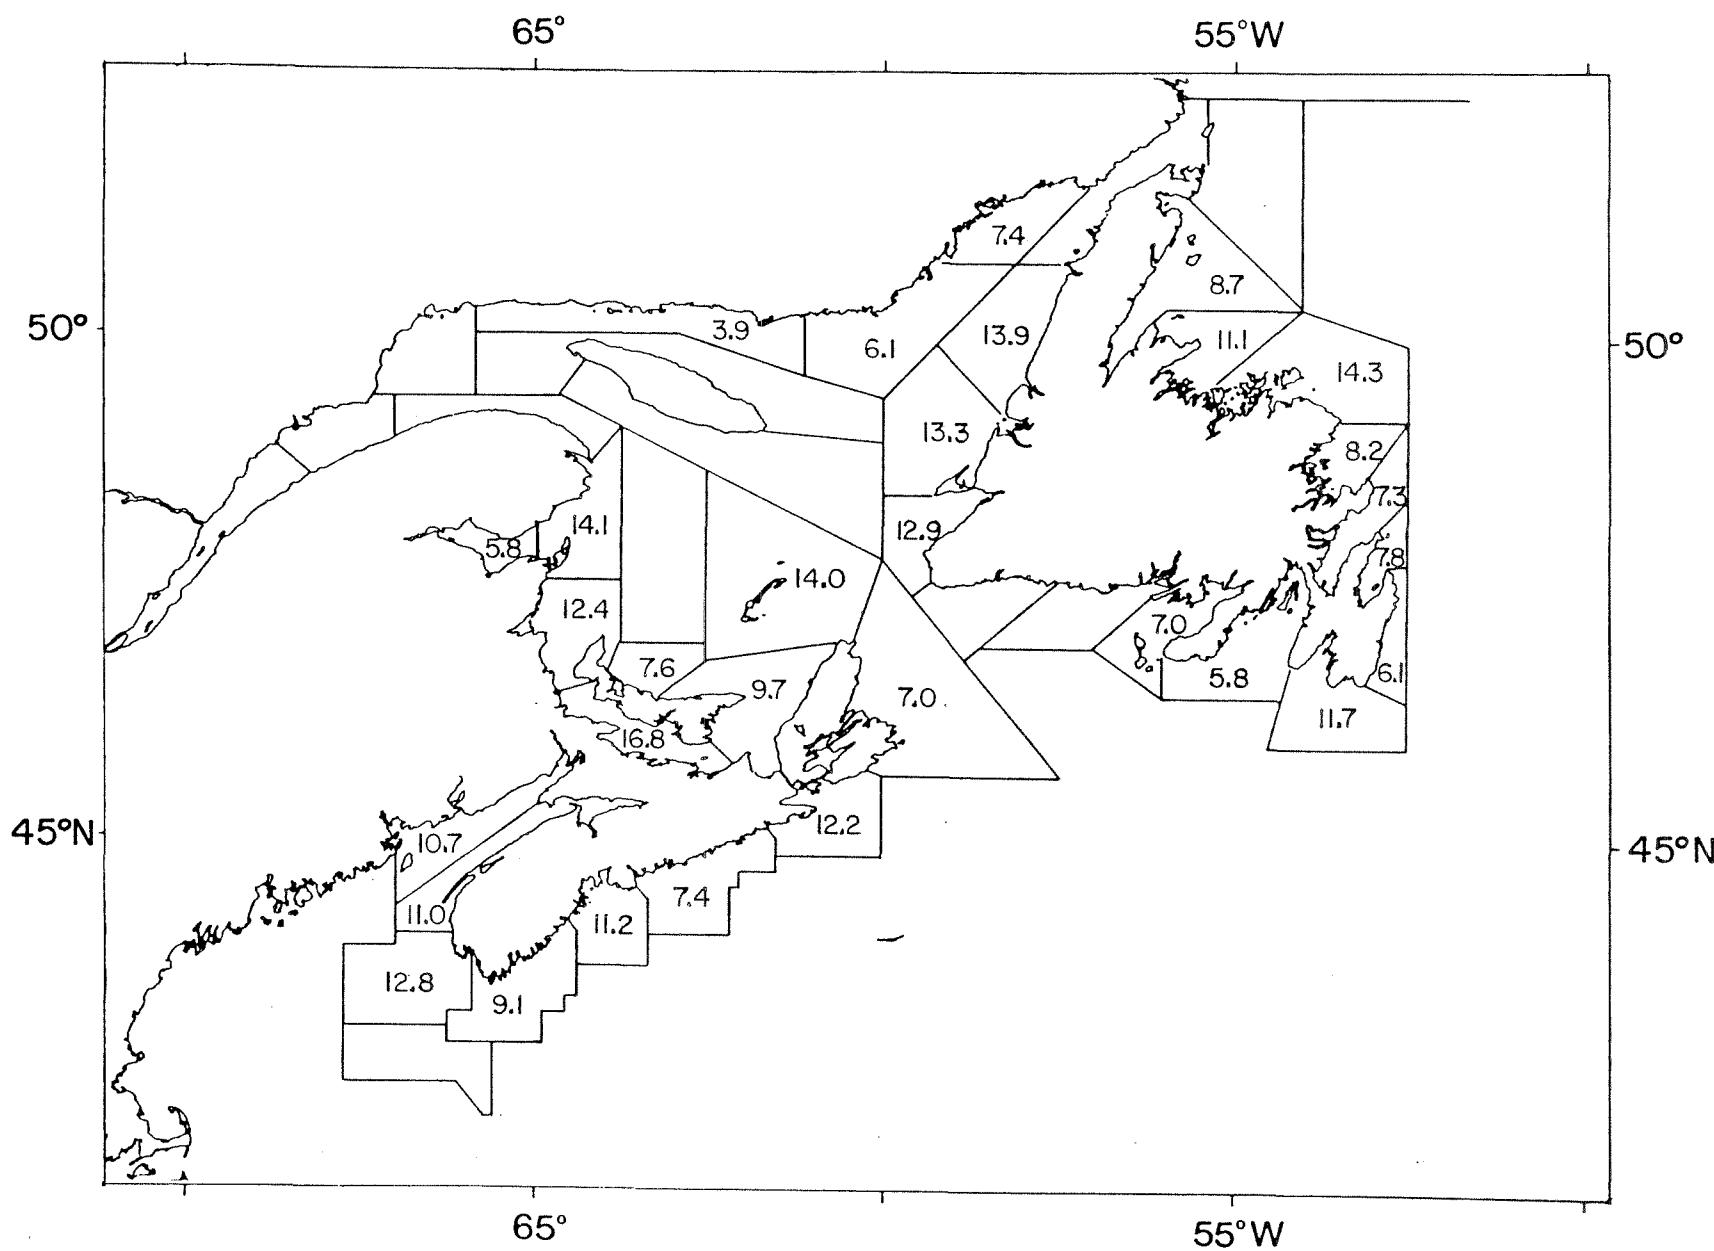

Figure 10. Chart showing grand mean August temperatures by Unit Area (lower depth range).

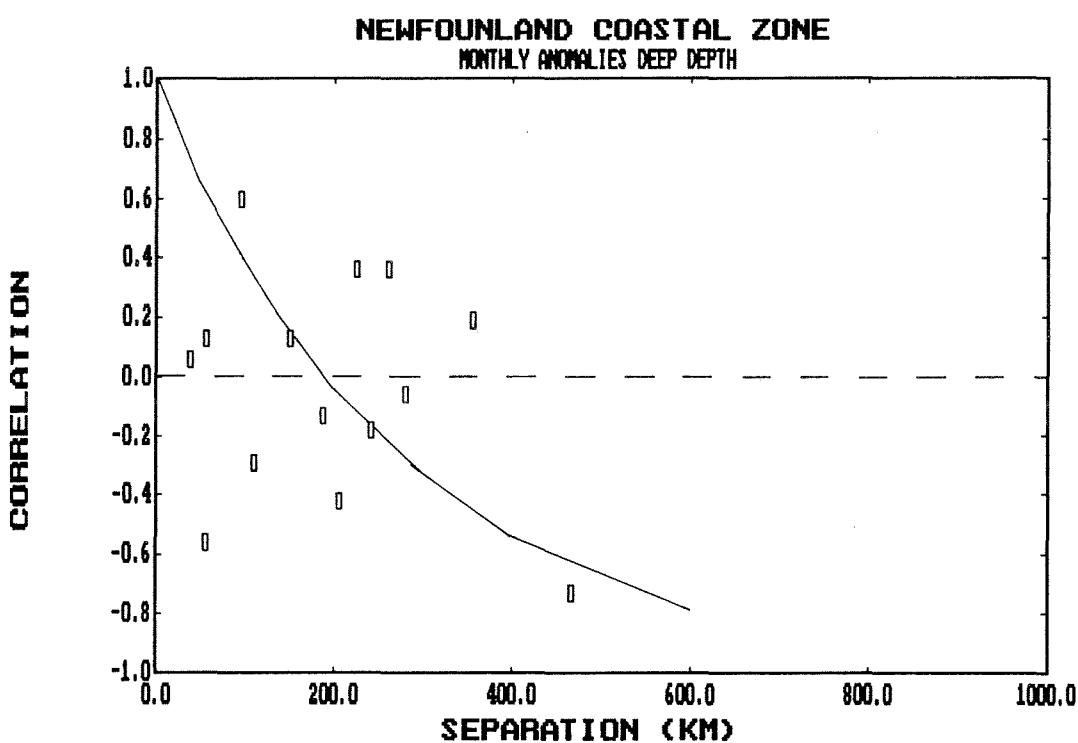

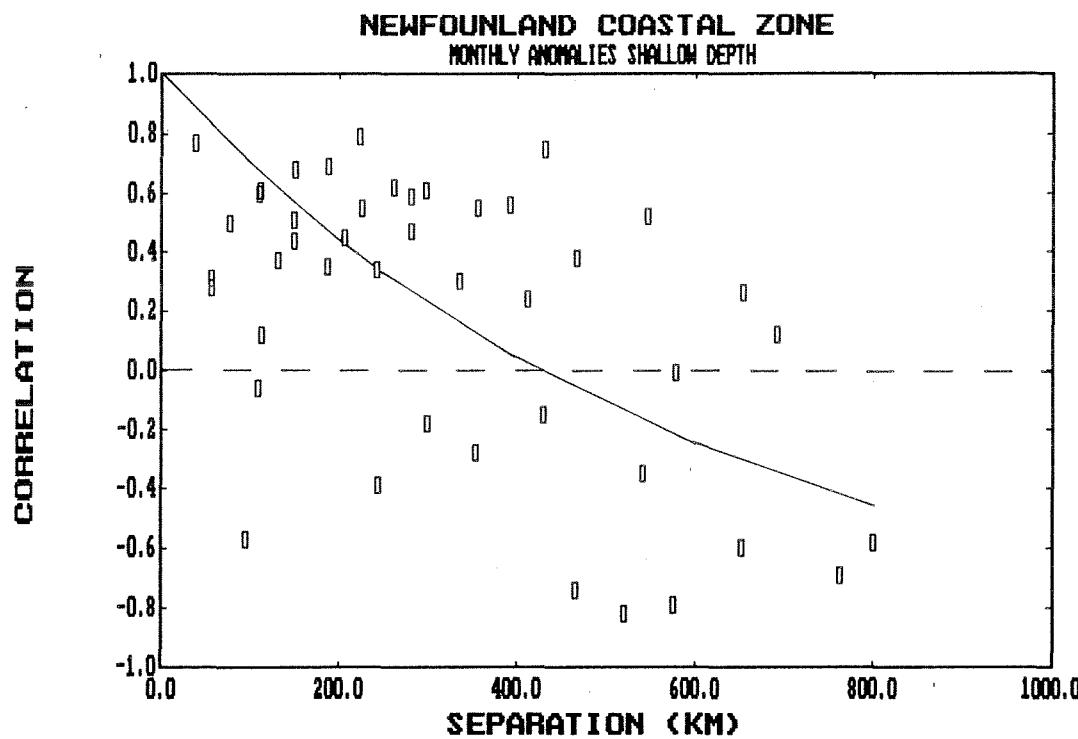

Figure 11. Correlations as a function of separation for the Newfoundland Coastal zone, shallow and deep layers. Correlations are based on monthly anomalies. The least squares fits of $2e^{-kx} - 1$ are shown.

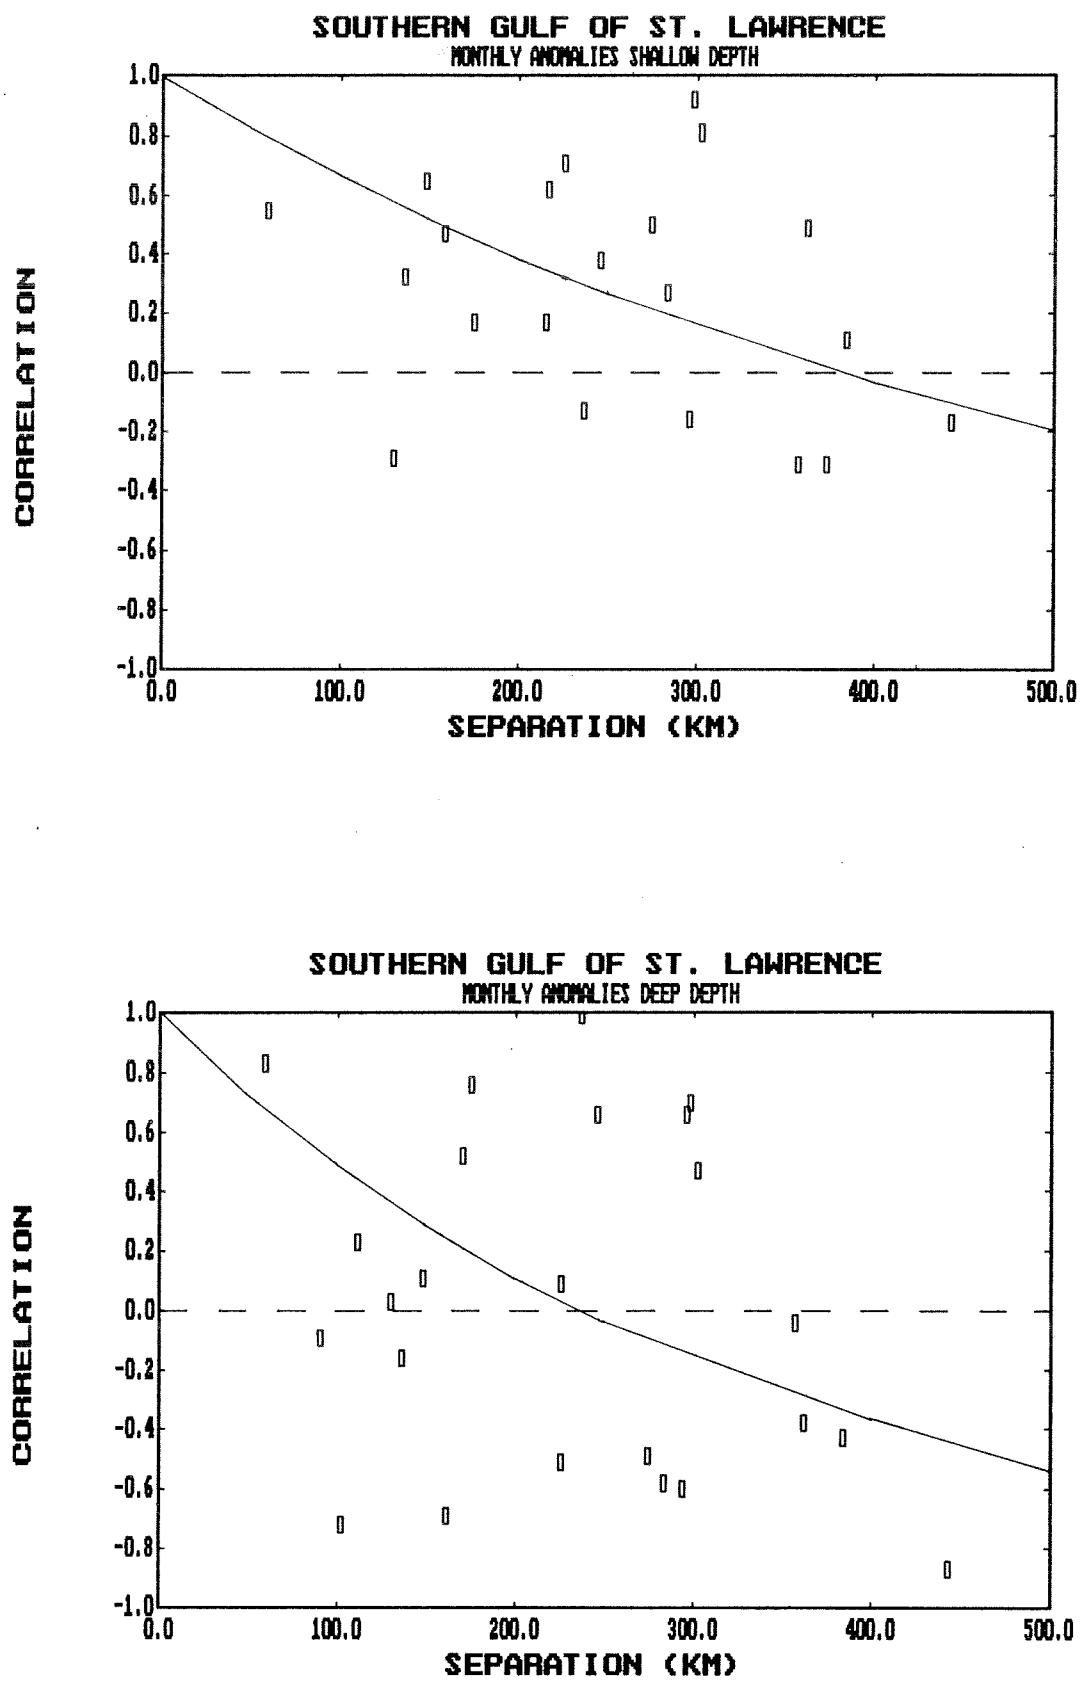

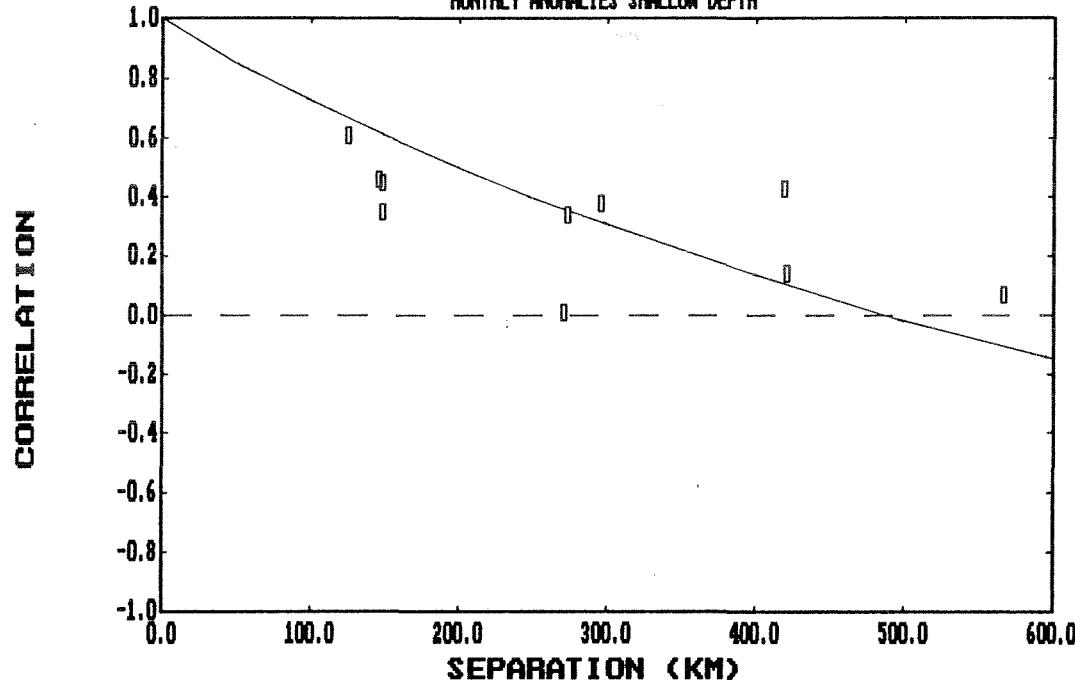

Figure 12. Correlations as a function of separation for the southern Gulf of St. Lawrence, shallow and deep layers. Correlations are based on monthly anomalies. The least squares fits of $2e^{-kx} - 1$ are shown.

Appendix D. Description of the LTTM data products archived on magnetic tape.

On magnetic tape archived in the Bedford Institute Computer Centre and available through Doug Gregory, Physical and Chemical Sciences Branch, Department of Fisheries and Oceans, Dartmouth, Nova Scotia, are stored copies of key programs used, actual four-hourly time series (inputs), monthly time series (outputs), both monthly averages and monthly anomalies, together with statistical products. The statistical products include the number of 4-hour observations by month, the long-term grand monthly means, and standard deviations, within months, within a particular month, between months, and in total.

Also archived with Doug Gregory at Bedford Institute are listings of the above statistical products as well as of the correlation matrices.
