## INTRODUCTION

This report presents the results of gold assays on samples collected during 1992 under project C1.311 (Placer Mineral Potential off Northeast Newfoundland), part of the Canada-Newfoundland Cooperation Agreement on Mineral Development (1990-1994). Sampling regions are presented in Figure 1. The samples were obtained in the course of two cruises. The first (cruise 92301) was a combined beach and nearshore program with limited work from a chartered fishing vessel (*MV Nicholas & Paul*) described in the cruise report by Edwardson et al. (1993). The objectives of this program included assessment of placer gold potential in coastal sediments proximal to known onshore gold occurrences in the Gander Bay, Dog Bay, New World Island, Green Bay and Baie Verte areas. The second cruise (*CSS Parizeau* 92042) was an extensive marine survey and sampling program with multiple objectives, including new information on the late- and postglacial stratigraphy of sediment packages in several fjord basins (Bay of Exploits, New Bay, Badger Bay and Green Bay) and the deep basin of Notre Dame Bay, in order to improve understanding of glacial processes that may have transported gold from onland bedrock sources onto the present inner shelf. Further assessment of the placer gold potential in seabed sediments from the region was another important objective.

## METHODS

Various sampling techniques were employed in this study. Beach samples were obtained with hand scoops or trowels and taken from the surface or very shallow depths (<0.1 m). Ekman and Ponar grab samplers were used to collect samples from an inflatable boat and a Boston Whaler in shallow nearshore waters during cruise 92301. A van Veen grab sampler was used to collect samples in deeper water (<52 m) from the *MV Nicholas & Paul*. During cruise 92042, most samples were obtained with a large-volume IKU grab. Some samples were collected using a van Veen sampler and a number of piston and vibracores were also obtained. Water depths at sampling sites represented in this data set ranged from 38 to 167 m. All grab samples were double-bagged and suitably labelled. Cores were split, photographed, and described. All samples and cores are archived at the Atlantic Geoscience Centre, Bedford Institute of Oceanography.

Sample analyses were completed by M-Tech Inc., Elmsdale, Nova Scotia, under contract from the Geological Survey of Canada (Kuryluk and Raymond, 1993). Samples were wet screened into six size fractions (Figure 2, Table 1). The screen sizes used were Tyler designations, as follows:

- 10 mesh – 2.00 mm,
- 20 mesh – 0.84 mm,
- 60 mesh – 0.25 mm,
- 100 mesh – 0.15 mm,
- 200 mesh – 0.075 mm.

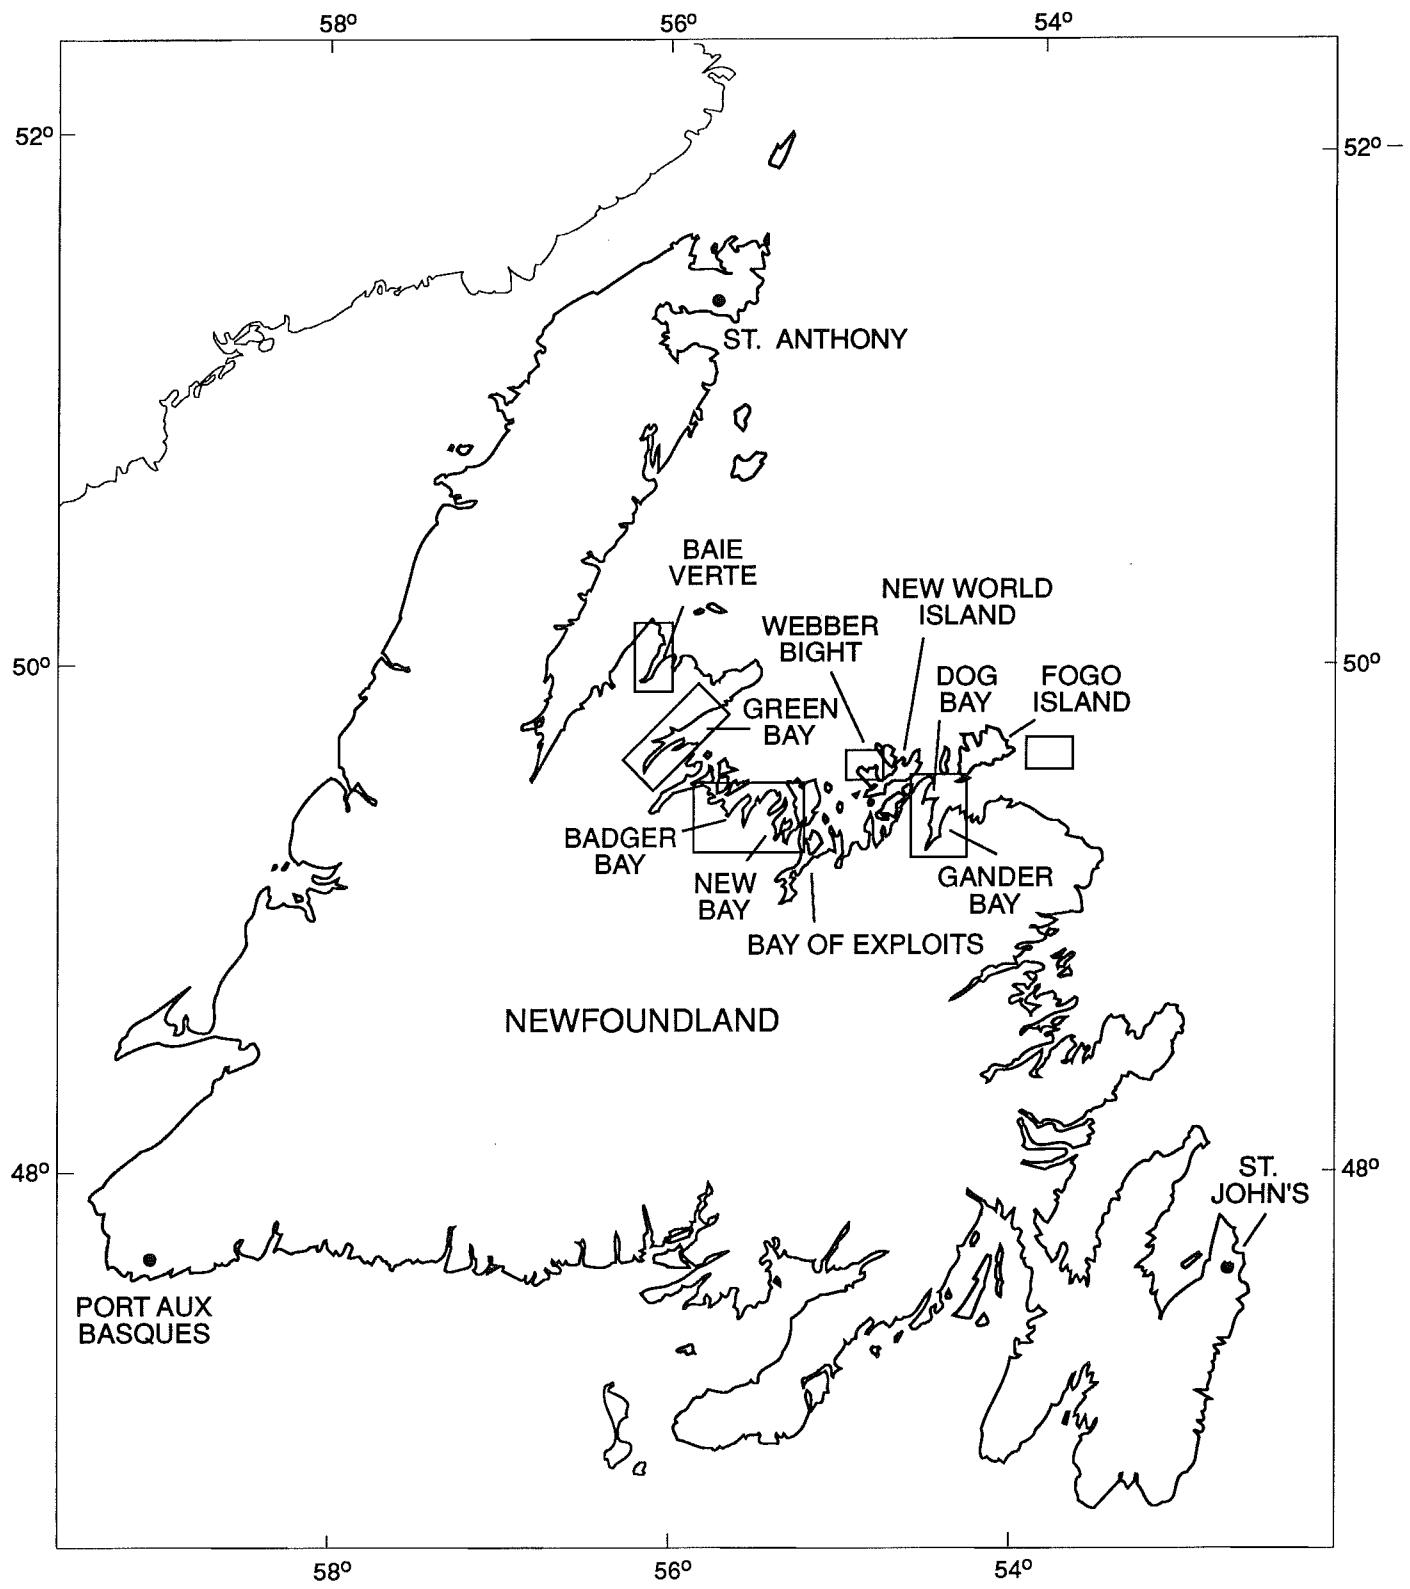

Figure 1. Areas of sample collection, shown as boxes, for cruises 92301 and 92042.

## FLOW CHART

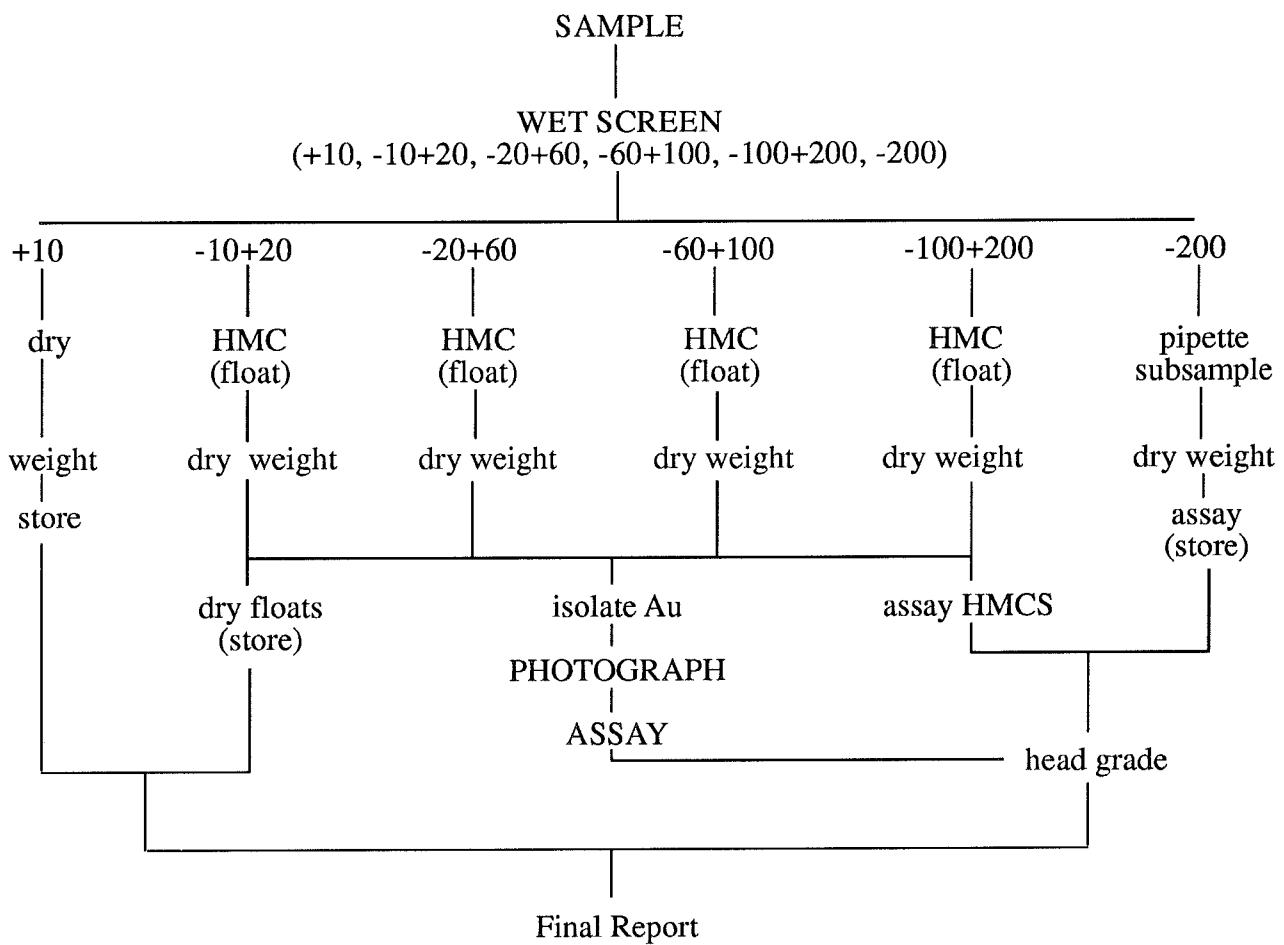

Figure 2. Flow chart depicting the processing of the sample (Kuryluk and Raymond, 1993).

The +10 mesh (>2.00 mm) fraction was dried, weighed and stored. The -200 mesh fraction (material finer than 0.075 mm passing through this mesh size) was analysed by pipette to determine its weight. This fraction was also subsampled for gold assay and the remainder was stored wet. The intervening fractions [-10+20 (0.84-2.00 mm), -20+60 (0.25-0.84 mm), -60+100 (0.15-0.25 mm) and -100+200 (0.075-0.15 mm)] were concentrated with the KMS [Kuryluk Separator] (Figure 3) to produce a heavy mineral concentrate (HMC) (specific gravity >3.5) and float from each fraction. The float material was dried and stored. The concentrate was examined with a binocular microscope to determine gold grain content and shape. Each concentrate was dried and weighed (Table 1). The four concentrates from each sample were combined for gold determination by fire assay with an Atomic Absorption finish, after the individual gold grains were isolated. The gold content of the isolated gold grains was determined separately, by Atomic Absorption.

A head sample result was calculated from the values obtained on the concentrate, -200 mesh subsamples, and isolated gold grains. This result was computed using two methods. The first (labelled "head grade" in Table 2) was calculated assuming no gold value on the float (all material excluding the HMC and the -200 mesh fraction), as follows:

$$HG_1 = (Au_C \cdot m_C + Au_{-200} \cdot m_{-200}) / m_T [1]$$

where HG is head grade,  $Au_C$  and  $Au_{-200}$  are the concentration of gold in the HMC (isolated gold grains and gold from the four concentrates) and -200 mesh fractions respectively, and  $m_C$ ,  $m_{-200}$ , and  $m_T$  are the weights of the HMC, -200 mesh fraction, and total sample. The second value (labelled "\*\*\*head grade" in Table 2), assuming that the gold concentration in the float was equal to that in the -200 mesh fraction, was calculated as follows:

$$HG_2 = (Au_C \cdot m_C + Au_{-200} \cdot m_{-200+F}) / m_T [2]$$

where  $m_{-200+F}$  is the total weight of the -200 mesh fraction and the float.

Several samples contained what appeared to be visible gold grains when observed through a 400-power binocular microscope. All grains observed are reported in Table 1. Each was isolated, photographed, and digested in Aqua Regia made to volume. Grain composition was determined by Atomic Absorption.

## RESULTS AND DISCUSSION

Sample depths range from 0 to 167 m. Of the 59 samples, 19 were collected from beaches in Gander Bay, Dog Bay, New World Island, and Green Bay and another 11 were taken from depths of 10 m or less.

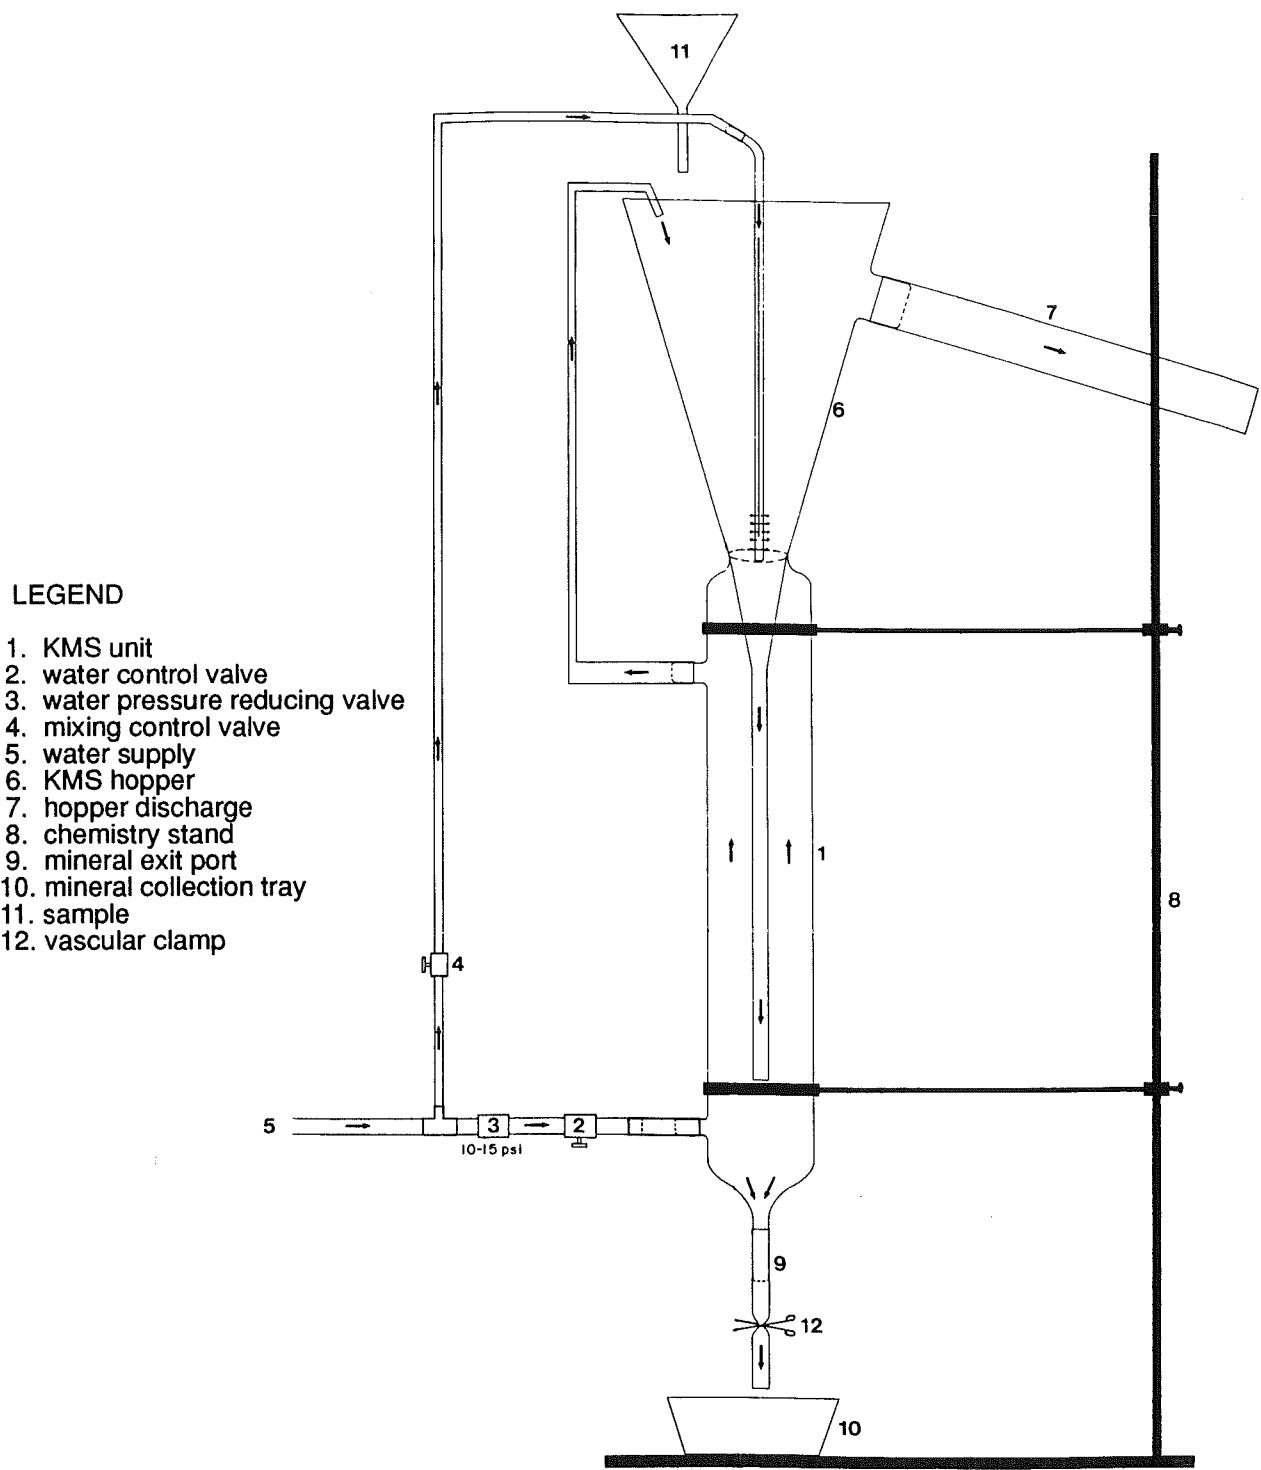

Figure 3. Kuryluk Separator. The sample is fed into the hopper and buoyed up by a stream of water. Heavy minerals sink when the stream velocity is decreased and gold is the first mineral to drop out because of its high specific gravity. Figure supplied by M-Tech Incorporated.

Head grades obtained in these samples range from <0.1 to 45 ppb Au [equation 1] and 5 to 1449 ppb [equation 2]. Our previous work in the area has demonstrated that a large part of the gold in many samples resides in the mud fraction (Shaw et al., 1990; Emory-Moore, 1991; Emory-Moore and Davis, 1992), suggesting that equation 2 may substantially overestimate the true grade.

The highest concentration in this data set is from a nearshore sample at Victoria Cove in Gander Bay. Several samples from this beach and Rodgers Cove to the west show elevated values of gold. Comparable values were also found in several samples from a core obtained in 52 m water depth in Deer Cove, Baie Verte, the area yielding the highest values in samples collected earlier in the project (Forbes et al., 1992).

Other areas showing elevated gold values include parts of Dog Bay, one or two sites along the east side of outer Green Bay, and deeper seabed sites east of Fogo Island (Table 2). Figure 4 shows the distribution of head grade values with water depth. While this shows some evidence for concentration of gold at present sea level, there are no other unambiguous patterns in this plot. Elevated values of HG<sub>2</sub> (at 48 and 71 to 84 m off Fogo Island and at 74 m off La Scie) suggest that further investigation in those areas may be warranted. In particular, earlier work under this project off La Scie (Shaw, 1991) has revealed elevated gold concentrations in some samples. The peak in the distribution of HG<sub>1</sub> at 52 m reflects the relatively high values in the core from Deer Cove (sample 92042-021).

Five samples of isolated grains returned values lower than the detection limit for gold. Six others, with grain sizes ranging from 0.14 to 0.46 mm, yielded values from 2.8 to 19  $\mu\text{m}$  Au. All samples were also assayed for silver and copper (Table 3). In addition to the copper, gold, and silver, it appeared from visual examination that several samples may contain cassiterite, chalcopyrite and magnetite. The differing grain morphologies suggest a range of transport histories.

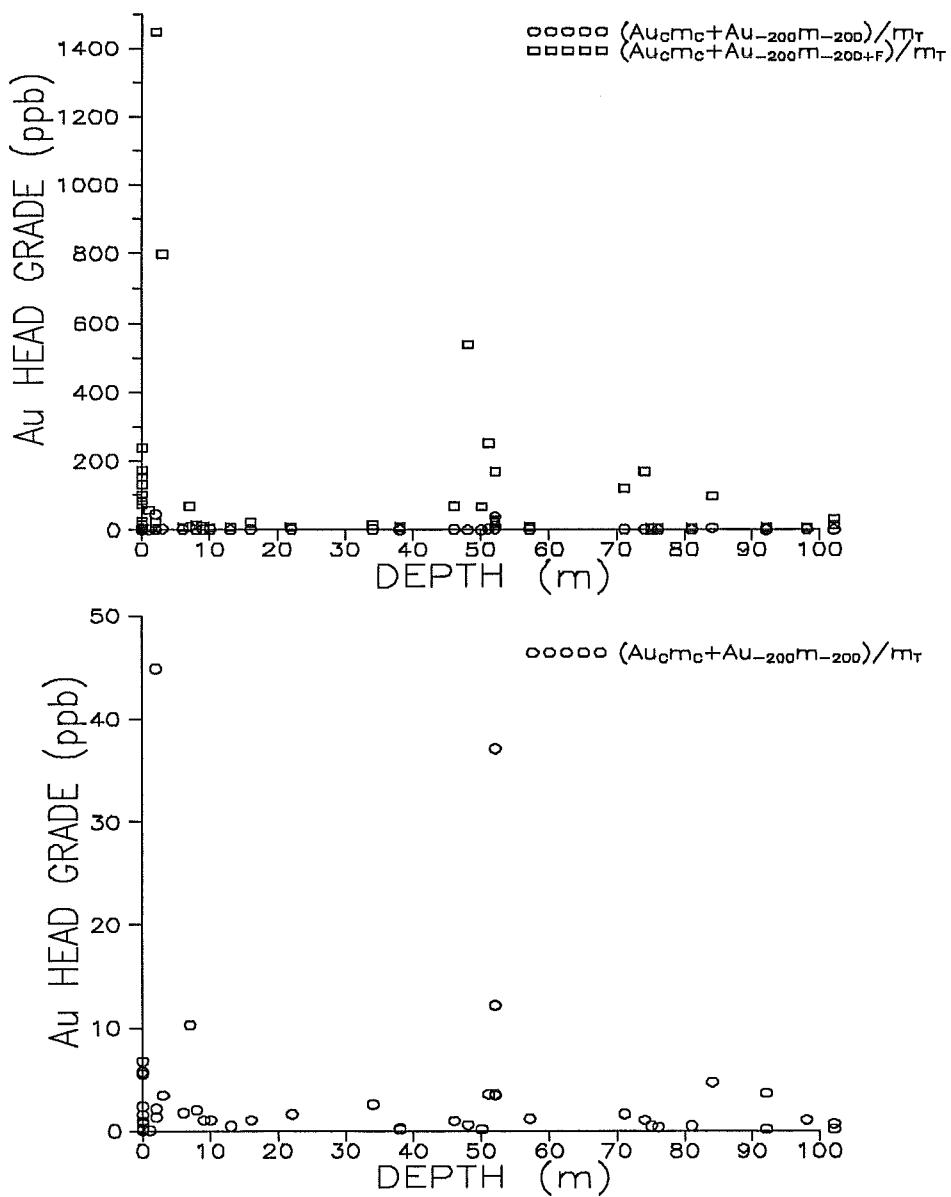

Figure 4. Head grade of gold in relation to water depth.
