# SEASONALLY ADJUSTED ECONOMIC INDICATORS 1947-1955 

(An Outline of Problems and Methods)

Reference Paper No. 77

Published by Authority of
The Right Honourable C. D. Howe, Minister of Trade and Commerce

## FOREWORD

The purpose of this reference paper is to provide, on a seasonally adjusted basis, about seventy economic time series for the post-war years 1947-1955; and in addition, to bring together a more complete discussion of the sources, methods, uses, and limitations of these data than was possible at the time the series (for recent years) were first released in the February 1956 issue of the Canadian Statistical Review.

The early recognition and interpretation of economic developments requires the use of monthly of quarterly data. However, basic movements in the economy are often obscured by large month-to-month or quarter-to-quarter seasonal (or intra-annual repetitive) fluctuations. Thus, when it is important to establish the direction of basic underlying movements in the economy, seasonally adjusted dat provide a powerful, almost indispensable, tool of analysis.

The present document describes many of the problems, techniques, assumptions, and limitations with which the economist or statistician must deal in the course of applying seasonal adjustments to economic time series for use in analysis. The material was prepared in the Research and Development Division by A.S. Rubinoff, with the assistance of E.C. West.

WALTER E. DUFFETT.
Dominion Statistician.

PART I

## CHAPTER I

## INTRODUCTION

This reference paper deals with the measurement of seasonal variation in Canada. The Canadian economy is subject to unusually wide seasonal swings - for example, total production normally shows a one-third increase from its low point in the first quarter of the year to the peak in the third quarter. Thus the measurement of seasonality is of interest in its own right. However, in Canada as elsewhere, the study of cyclical behaviour has absorbed an increasing share of the attention of economists and statisticians in recent decades. Monthly series in their original form show wide seasonal swings which often obscure underlying trends and baffle the analyst who seeks to study cyclical behaviour or to interpret the significance of current economic developments. Accordingly, seasonally adjusted series, which abstract from seasonal change, are generally acknowledged to be an essential tool in business cycle analysis.

## Historical Review

The presentation of seasonally adjusted statistics is not a new departure for the Dominion Bureau of Statistics. Seasonally adjusted data on production and employment were published in the old Monthly Review of Business Statistics, covering in the main the years 1919-1947 ${ }^{1}$. From January 1948
to November 1952 the Canadian Statistical Review published detail of the seasonally adjusted index of industrial production. The index of industrial production was then being revised and it was decided to cease publishing seasonally adjusted material, pending new techniques of computation and clarification of post-war seasonal patterns. The release of quarterly estimates of National Accounts in November 1953, included seasonally adjusted quarterly series of the components of Gross National Product, National Income and Personal Income. Experimentation proceeded on monthly series, and in the February 1956 issue of the Canadian Statistical Review about seventy economic indicators were released, on a seasonally adjusted basis, for the current months.

This reference paper includes data for most of the post-war period for these seventy series and describes the methods used in computing the results. Research on new methods and techniques is still proceeding, and from time to time it is planned to issue additional series as well as any improvements in already published material. One of the most promising developments is the programing of the computation of seasonally adjusted material on electronic computers; these developments are being followed carefully in continuing research on this problem.

## CHAPTER II

## DEFINITIONS AND CONCEPTS

Economists have long viewed time series, that is quantitative records arranged in chronological sequence, as a synthesis of four distinct types of concurrent change. These are classified as secular, cyclical, seasonal and random or irregular movements. Secular movements are defined as those smooth regular long-term movements of a statistical series whose persistence is associated with some basic underlying characteristic. The concept covers both positive and negative changes. Cyclical movements have been the subject of intensive study by the National Bureau of Economic Research and the definition set out in their publications may be quoted here;
"'Business cycles are a type of fluctuation found in the aggregate econoraic activity of nations that organize their work mainly in busi-

1. See Monthly Review of Business Statistics, February 1944 and May 1947, for seasonally adjusted sertes 1919-1946.
ness enterprises: a cycle consists of expanslons occurring at about the same time in many economic activities followed by similarly general recessions, contractions and revivals which merge into the expansion phase of the next cycle; this sequence of changes is recurrent but not periodic; in duration, business cycles vary from more than one year to ten or twelve years; they are not divisible into shorter cycles of similar character with amplitudes approximating their own."2

Seasonal movements are those intra-annual movements persisting from year to year with similar patterns of timing and amplitudes and having some stability in the structure of the industry or area under observation. Random or irregular movements are those which occur from time to time without any clear pattern in timing or amplitude. From the view-
2. A.F. Burns and W.C. Mitchell, Measuring Business Cycles, National Bureau of Economic Research, New York, 1946, page 3.
point of the theorist they are accidental; examples are disturbances caused by floods, strikes or wars. Random may be distinguished from irregular factors in that we have some knowledge of the latter and none of the former.

Time series analysis consists of isolating one or more of the elements that make up the composite movement of the series. Sometimes the object is to study the seasonal, secular of cyclical element in isolation, but more often to study the trend and cycle in combination.

Seasonal movement is distinguished from secular by its oscillating character, from cyclical by
being confined within the limits of a twelve-month period, and from random or irregular by the fact of its regular recurrence. For purposes of devising a technique of measurement, seasonal variations are defined as relatively stable fluctuations that occur in a repetitive fashion within each year for a number of years. This concept of stability embraces both constant and moving seasonals. The concept has to be further modified to take account of shifts which may occur in the timing or amplitude of these fluctuations. Seasonally adjusted time series are a combination of trend, cycle and irregular movements with the element of seasonal variation removed.

## CHAPTER III

## SEASONALITY - ITS CAUSES AND CHARACTERISTICS

The notion of seasonal variation is inherent in the nature of changing seasons, altnougn numan institutions also produce seasonal variations in economic activity. Changing seasons bring changing temperatures, precipitation and length of day and night; in turn these affect conditions of production and demand for many commodities. In Canada, for the most part, the growing season for crops is restricted to spring and summer months. The amount of pasture available throughout the year helps to determine the breeding and slaughter of livestock and affects the output of dairy products. Fishing, trapping and forestry are greatly influenced by climatic conditions. In northern climates, construction slows up markedly with the advent of cold weather and waterways and harbours are closed to shipping during the winter months. The demand for fuel, clothing and even for some foodstuffs varies with seasonal changes in temperature and precipitation.

Some seasonal changes are based on social and institutional factors. Law and custom ordain the observance of certain holidays and religious festivals. Behaviour in social and business life follows certain patterns fixed by long-established usage. Indeed one of the most pervasive seasonal factors in monthly time series is the conventional calendar which makes February ten per cent shorter than January and April nearly three per cent shorter than March. Thus conventional seasons are superimposed on climatic seasons to produce fluctuations recurring year after year and having broadly similar patterns of timing and amplitude. Seasonality at any stage of the economic process, from the supply of raw material to the sale of the final product, enforces corresponding fluctuations in a wide chain of interdependent activities. Thus seasonality radiates out from its point of origin.

As has been noted, these seasonal fluctuations are based upon relatively stable factors such as climate or social institutions. Because of this rel-
ative stability, the seasonal element as such may be isolated and measured. However, variations do occur in the stability of these factors, and these variations give rise to many of the more difficult problems associated with the process of seasonal measur ement. For example, the transition from. season to season does not take place at precisely the same time each year and the same season will register widely varying rates of temperature and precipitation from year to year. Conventional seasons also display temporal changes, the shifting date of Easter being the classic example.

Temporal shifts in seasonal patterns may arise from a variety of other reasons. The decisions of regulatory bodies frequently introduce discontinuities in economic time series. Seasonal patterns of production and sales of many consumer items were wholly or partially suppressed during World War II and remained in abeyance for several years after normal peace time production had been resumed, so great was the demand accumulated over the war years. The rapid development of a new resource or an abrupt change in technology may also make for discontinuity in economic time series.

While secular changes in climate may be ruled out of consideration for practical purposes, secular changes in other seasonal factors are constantly taking place. A decline in the relative importance of agriculture will modify seasonal patterns in the economy as a whole, as will a shift in the geographical distribution of industry in a country extending over several climatic zones. Changes in technology may alter the importance of climatic factors. Custom and habit change over time. With a rising standard of life, tastes that were once the prerogative of a small social group become diffused among the mass of consumers, thereby altering the area of demand that is influenced by fashion and style. A dampening down of seasonality may come about as a result of conscious effort by business or by government. In general, it might be expected that many of the long-run secular forces would be towards dampening
down or minimizing seasonal variation, insofar as seasonal fluctuations represent a cost to the firm in unused capacity, of a cost to society in unutilized resources.

Seasonal fluctuations are not always independent of cyclical influences and sonetimes respond to changing levels of activity and changing prospects for output, prices and profits. When prospects are good, businessmen may be willing to produce for stock during the seasonal low in demand but unwilling to do so if prospects are deteriorating. Thus
cyclical influences may tend to intensify or to otherwise alter seasonal fluctuations.

Changes in seasonal variation brought about by the impact of secular or cyclical forces may have some regular pattern. If so, these changes can be measured, allowed for, and if necessary extrapolated into current periods. However, when these factors operate to introduce changes that have no clear pattern, then economic time series will not respond to a mechanical measure for seasonal variations and individual cases must be analyzed to determine the possible nature and direction of these changes.

## CIIAPTER IV

## THE NEED FOR SEASONALLY ADJUSTED SERIES

It may be argued that seasonal variations may be judged simply by examining the unadjusted data. For example, the amount of seasonal variation in the construction industry could be deduced by comparing the month of highest employnent and the month of lowest employment in any given year. However, this would be a true measure of seasonality only if the industry were not in a stage of growth or decline for secular or cyclical reasons. Furthermore, the use of the unadjusted data would not bring to light any changes in seasonal variations as they occurred through time. Thus, seasonally adjusted series are a useful tool for those who are primarily concerned with the study of seasonality itself.

The major share of attention, however, has been devoted to the measurement of seasonality as an essential tool in the analysis of business cycles. Experience has shown that the cyclical behaviout cannot be analyzed successfully on the basis of annual data. At the same time monthly or quarterly data are difficult to interpret if an element of seasonal variation is present. If the seasonal element is sufficiently large, the underlying cyclical movement may be lost to sight. This point is illustrated in Chart I, which depicts a situation where a normal seasonal change occurred in the opposite direction to the underlying non-seasonal (trend-cycle) movement and where the seasonal change was larger than the non-seasonal change. The series shown is without jobs and seeking work.

A small non-seasonal decline in unemployment between mid-1954 and the spring of 1955 took place at the same time that a large normal seasonal increase occurred. Thus, unemployment as shown by the unadjusted data reached a post-war peak in March of 1955 even though there had been a slight improvement in the underlying situation during the preceding six months.

The economist or statistician who attempts to interpret business conditions is always concerned to know the direction in which business is moving and it may be his task to forecast the future on the
basis of emerging trends or tendencies. For this purpose it is often necessary to make comparisons of the current month with some preceding month or other point in time. Seasonal variations completely invalidate comparisons of the current month with some other month of the same year, and the underlying trend or cyclical movement cannot be discerned clearly unless this seasonal element is removed ${ }^{1}$.

In the course of extensive research on the business cycle a number of different methods of establishing and measuring the trend-cycle have been devised. It is convenient at this point to examine these methods of establishing a tuend-cycle, to discuss their limitations and to compre the results with seasonally adjusted time series.

## (1) The Twelve Month Centred Moving Average

Sone notion of the underlying trend-cycle in an economic time series may be derived by running a twelve month moving average through the original data. This averaging procedure removes the seasonal but it is a rather crude approximation to the underlying trend-cycle in certain circumstances. A cyclical peak or trough occurs at a given point in time. Because the twelve month moving average gives equal weight to all months, the impact of the cyclical turning point month will be spread out over the six months preceding and following. Thus the twelve month moving average is relatively insensitive to sharp cyclical movements: Moreover, a single irregular event will affect the average for six months prior and six months subsequent to the event. It is due to this characteristic-smoothness - that most authorities consider the twelve month centred

[^0]
## WITHOUT JOBS AND SEEKING WORK

moving average does not trace effectively the exact timing of the cycle nor its exact amplitude from peak to trough. Furthermore, the moving average, being always six months behind the current period, is not a tool that can be used to analyze current data.

## (2) Year to Year Links

Perhaps a more common technique is the use of year to year comparisons or links as they are often called. An attempt is made to eliminate seasonality by comparing the same periods, that is July with July, August with August and so on. The series of percentage changes in each comparison is used to establish the current trend. No subjective decision is involved in this procedure and it is sometimes suggested that the link method is a better alternative than seasonal adjustment. However, there are a number of basic objections to this technique.

The first difficulty with year to year links is that the user is not really able to make comparisons involving seasonality. In other words, while it is possible to compare February of this year with February of last year and July of this year with July of last year, the user is unable to compare February of this year with July of this year. In fact the only valid comparison that can be made in raw data is on the February-February type of basis and such a comparison must be interpreted within rather
severe limitations. However, it may be important at times to make comparisons between February and July, for example during turning points in business activity or where one wants to compare the current month with the peak or trough of some recent cycle. The second difficulty is that the user cannot measuse the extent of seasonality involved by using the link method. How much of the unemployment in winter months (see Chart I) is the result of purely seasonal factors cannot be established by the link method.

Finally, the relationship of year to year comparisons or links to emerging economic trends is a rather complex problem. It may be asked whether it is possible to assess the direction of movement in the future by studying past movement in the links. For example, if July over July was up $10 \%$. August over August up $9 \%$, could the user not anticipate that September over September might be up $8 \%$ ? Such a conclusion would not be warranted and for a number of reasons. The August over August change of $9 \%$ tells only that this change took place within the intervening eleven months; it does not tell when that change occurred. Nor does it tell whether that change was due to secular, cyclical, seasonal or irregular factors. Also, the narrowing in the year to year links cannot readily be interpreted as a slowing down in the rate of increase or as an actual decline.

Some of the difficulties implicit in the relationship of links to emerging trends may be elaborated.

1. The base period for the comparisons may be erratic. Thus, in the previous example, July and August of last year may have been very poor months, while september may have been a more normal month. In such a case, the July and August links would appear much more favourable than in normal circumstances. It may well be that the September over September link, based on normal movements, would not show any increase whatever. Thus the user of the link method must consider not only current months but also note any erratic movement in the base period.
2. Even if there were no unusual event in the base period, the user would still run into difficulty when a turning point was reached. For example, if July of the preceding year had been the trough of a cycle, and pick-up occurred in August, then the July over July link would probably give a too favourable comparison, while the August over August link would show a slowing down in activity, a result which would reflect simply the base of the year before, rather than underlying current conditions.
3. Even if there were nothing so drastic as a change in turning point, the result would be affected by a change in slope in the base period; in such a case the rate of change
from one month to the next in the base period would be different and current percentage links would reflect this difference.
4. Even assuming that none of the limitations already mentioned were present, the user would still be unable to ascertain the current position if the results showed a change in the rate of percentage links. For example, if the month-to-month links showed diminishing increments going gradually from plus 10 per cent to plus 2 per cent, he would not know whether there was (a) a slowdown in the rate of expansion, (b) a levelling in activity, or (c) a decline in activity.

There is in fact a relationship between year-toyear links and the moving average technique previously discussed; one writer ${ }^{\text {a }}$ has pointed out that a year-to-year comparison is analogous to the mathematical procedure of taking the first difference of a twelve-month moving total, the result being centered back six months. At best a year-to-year compar1son portrays an underlying situation that developed six months earlier.

The index of industrial production shown below illustrates the time-lag involved in the use of year-to-year links as compared with seasonal adjustment.

1. F. R. Macaulay, The Smoothing of Time Series, National Bureau of Economic Research, New York, 193i, page 134.

Industrial Production

| Date | Index seasonally adjusted | Index unadjusted | Per cent change year/year | Date | Index seasonally adjusted | Index unadjusted | Per cent change year/year |

| J | 248. 9 | 257.5 | + 8.1 | D..................... | 250.4 | 240.6 | + 2.2 |

While the peak of activity, seasonally adjusted, was recorded in mid-1953, it was not until December 1953 that the year-to-year comparisons showed a decline. During the period when the rate of increase from month to month was diminishing, as shown by the links, it was impossible to establish whether this implied a slowing-down in the rate of increase, a flattening of activity, or a decline in activity. It was fully six months after the peak had been reached that the user could have been certain that a decline had in fact occurred. The use of the seasonally adjusted data revealed the underlying situation (e.g. that a turning point had occurred) a full half year earlier.

Another facet of the problem of interpreting current trends with year to year links rather than seasonally adjusted data is in connection with the checking of forecasts. In such cases, the projected figure is adjusted for seasonal variation and compared with current data, likewise adjusted. If the results appear inconsistent after considering other known factors, then a reassessment of the forecast would be made. Sometimes results appear reasonable on the basis of links which do not appear reasonable when adjustment is made for seasonal variations. The following example illustrates the point.

|  | Data unadjusted | Year to year percentage change | Data seasonally adjusted |
| :---: | :---: | :---: | :---: |
| 1954 1Q .................................................................... | 200 |  | 250 |
| 2Q ................................................................. | 300 |  | 250 |
| 3Q .................................................................. | 200 |  | 250 |
| 4Q .................................................................... | 300 |  | 250 |
| 1955 1Q ................................................................. | 175 | - $12 \%$ | 225 |
| 2Q ... ............................................................... | 190 | - $37 \%$ | 140 |
| 3Q ................................................................. | 85 | - $57 \%$ | 135 |
| 4Q .................................................................... | 200 | - $33 \%$ | 150 |
| 19561 12 .................................................................. | 130 | - $26 \%$ | 180 |
|  | 250 | $+32 \%$ | 200 |
| 3Q (Forecast) .................................................... | 130 | + $53 \%$ | 180 |

Note. Assumed seasonal factors are: $1 Q-50,2 Q+50,3 Q-50,4 Q+50$.

In the above model a third quarter forecast of 130 is made on an unadjusted basis. On the basis of the movement of the year to year links this forecast appears reasonable. However, after seasonal adjustment is is obvious that this figure of 130 represents a break in the seasonally adjusted trend which drops from 200 to 180 . On this basis it appears that the forecast of 130 is too low and needs to be revised upward unless there is some knowledge of the economic situation that suggests a reversal of the previous trend in the seasonally adjusted series.

In one study of forecasts a writer compared results of forecasts of traffic made by railroad shippers with his own results which were based simply upon a projection of seasonally adjusted data'. In this study, the simple projection of seasonally adjusted data provided more reliable forecasts than
the informed knowledge of conditions expressed in quarter over quarter terms by the shippers.

In sunmary, seasonal indexes are necessary to give a good measure of seasonal patterns, past and present, for the use of those concerned with seasonality as an economic problem. For the analyst of business conditions, whether his primary concern is historical data, current economic conditions, or probable future developments, seasonally adjusted time series which effectively trace the trend cycle, the exact timing and amplitude of peaks and troughs, and the turning points from one phase to another, are an indispensable statistical tool.

1. T. Hultgren, "Forecasts of Railway Traffic, in Short Term Economic Forecasting, Princeton University Press, Princeton, 1955, DD. 363-380.

## CHAPTER V

## SEASONAL ADJUSTMENT - GENERAL PROBLEMS AND METHODS

## Problems in Seasonal Adjustment

Some indication of the problems of seasonal adjustment was given in Chapters III and IV, which discussed the character of seasonality, the difficulty of isolating the trend cycle from other elements in a time series, and the limitations of the various methods that may be used. It is sufficient to say here that discerning the trend cycle is one of the most important and baffling problems in the process of seasonal adjustment. However, the separation of irregular and random elements from seasonal factors also raises a nurrber of problems. Distinct but related difficulties arise from the nature of seasonality itself, namely the fact that seasonal patterns are subject to temporal change.

The separation of seasonal factors from random events would at first sight appear to present no problems. Random events are assumed to have a symmetrical distribution and if a series is available over a sufficiently long period of time, random events would tend to cancel out and have no net effect on the computation of the seasonal index. However, few series are available over so long a period of time as to give full validity to this assumption. So far as irregular events are concerned, some impart a known bias to a series; for example, strikes operate to reduce employment series.

It has already been noted that seasonal patterns can vary over time for a variety of reasons. Apart from year to year disturbances in the timing and amplitude of seasonal swings, seasonal patterns undergo secular changes and sometimes respond to cyclical influences. As suggested above, the concept of stability in seasonal variation embraces movements over time that have some reasonably regular pattern. This pattern may take the form of constant or fixed seasonals. For example, if all the various influences impinging on the seasonal factor for the month of June for employment do not change, the measure of seasonal variations for June will be a constant over the period of time. On the other hand, in the month of July, the institutional extension of vacations with pay may operate to steadily reduce the element of production for July and the seasonal factor will be stable but downward over a long period.

The application of fixed constant seasonals in the situation where there is stable downward (or upward) movement of this character operates to introduce choppiness into seasonally adjusted series because the seasonal index over-corrects at some point of time under-corrects at another. Here, the use of moving seasonals is indicated. There are cases where the changes in seasonal patterns over time do not have this degree of regularity; in such cases the application of a purely mechanical procedure is not warranted and individual cases must be fully analyzed to determine the inherent real nature of the seasonal variation.

## Method of Seasonal Adjustment

The methods of seasonal adjustment in common use are: the percentage-of-trend line, the link relative, the graphic and the ratio-to-moving-average. The choice of a method depends in the final analysis on the conditions under which the work is to be performed, these conditions in turn being a function of the primary data and the amount of time and skill that can be devoted to the process. The method chosen must be fairly simple to compute so that large numbers of series can be adjusted. It must be sufficiently flexible to meet a multitude of technical problems. It must be reasonably objective and reach agreed scientific standards. At the same time, it, should give scope to the trained analyst to apply his knowledge and Judgment.

A combination of the graphic and the ratio-to-moving-average method was finally evolved as the technique of seasonal adjustment in the Dominion Bureau of Statistics. The percentage-of-trend line was ruled out because the major changes apparent as an aftermath of World War II made obsolete any trend line derived from earlier historical data. The link relative method proved unadaptable for varying rates of growth and unworkable in time series showing turning points as well as moving seasonals.

The method finally selected, the combination of graphic and ratio-to-moving-average, met the criteria set out above. It is fairly easy to compute as the following example will show. It can be adapted to meet technical problems and proved flexible in dealing with series featuring varying rates of growth as well as turning points. It is reasonably objective and has been used by most of the leading authorities in this field. At the same time it leaves room for the exercise of judgment and the application of knowledge.

In the method of seasonal measurement adopted by D.B.S. the trend-cycle is first approximated by running a twelve month moving average through the raw data. This leaves seasonal, irregular and random factors as a residual; and in those cases where the moving average is insensitive, some residual cycle may also be present. Irregular factors may be analyzed and removed leaving largely seasonal movements. The seasonal factors are derived by the use of moving averages and graphic methods, and finally the trend-cycle calculated a second time by the application of the derived seasonal factors to the raw data. This second calculation is a much closer approximation to the trend-cycle than the first. Recent developments in the field of seasonally adjusted data by electronic computers have carried this general approach of successive approximations a stage further.

## Outline of the Metlod Adopted

The general approach to the seasonal adjustment of monthly series adopted by the Dominion

Bureau of Statistics is set out below:
(1) The Twelve month moving total of the original data is calculated.
(2) The two month moving total of the twelve month moving total is then computed.
(3) The two month total of the twelve month total is divided by 24 to give a centred twelve month moving average.
(4) The original data are divided by the centred twelve month moving average; these are the ratios-to-moving average.
(5) On individual charts for each of the twelve months of the year are plotted all the observations (ratlos-to-moving-average) for that month, that is all the Januarys on one chart, all the Februarys on another, and so on for the twelve months. The plotting of each individual deviation (or ratio) is done in chronological order. This ylelds a time serles of ratios-to-moving average for all months.
(6) A three term moving average of the ratios-tomoving average for each month is computed and marked on the chart for each month; this is a guide to the next step.
(7) For each successive month a free hand curve is drawn to fit the data.
(8) For each month of each year the readings of the free hand line are taken.
(9) The readings for the twelve calendar months of each year are summed and adjusted to equal twelve hundred; these adjusted series are the final seasonal indexes.
(10) The original data are divided by the seasonal indexes to derive the seasonally adjusted results.
(11) Tiet charts are drawn to check for residual seasonal.
The various steps outlined above are illustrated in the example on pages $16,17,18$ and 19 which deal with the complete seasonal adjustment of Live Applicants for Employment.

Live Applicants for Employment - Concluded
Seasonal adjustment

The singificance of each step may be explained as follows: Step 1, 2 and 3 are taken in order to derive the twelve month centred moving average which is the first approximation to the trend-cycle. A twelve month moving average eliminates the seasonal variation in that each average includes twelve months. An uncentred twelve month moving average would represent the first of each month and would therefore not be fully representative of the entire month. It was decided to centre the twelve month moving average by taking an average of the calculation for each, month and that of the succeeding month. In other words, the first twelve month moving average is centred at say July 1 st, the second twelve month moving average on August 1 st . An average of the two is centred at July 15 th and it is thus more representative of the month. Taking a two month moving total of a twelve month moving total is only a short hand method of deriving a centred result.

Dividing the original data by the centred twelve month moving average gives a first approximation to the seasonal and irregular components. Since the original data represent a composite of the trend, cycle, seasonal, and irregular and since the twelve month moving average represents trend, cycle and some irregular, then the ratio of the original data to the moving average gives a first approximation to seaconal components as well as some irregular.

The ratios are plotted by months to enable the statistician to discern the irregular events or any tendency for a seasonal factor to shift through time. Graphic presentation is of crucial importance in successful seasonal adjustment. The three term moving average which is run through the ratio-to-moving average are helpful in detecting persistent movements in the seasonal factors and act as a guide in ensuring that the free hand curve gives a reasonable fit ${ }^{1}$. The twelve seasonal indexes for each year are adjusted to equal twelve hundred in order that the sum of the seasonally adjusted data will approximate more closely the sum of the unadjusted data.

The final step, dividing the original data by the seasonal index simply removes the seasonal element from the original series thus leaving the trend, cycle and the irregular factors in the final result. The tier charts are used simply to check for any residual seasonal which may not have been adjusted out by all the previous steps.

## Underlying Assumption and Limitations

While the above description of the seasonal adjustment technique may appear fairly straightforward, it may be useful at this point to reiterate and elaborate on the assumptions and limitations involved in the process. The first assumption involved is that the seasonal factor itself is reasonably

[^1]stable and can be expected to repeat itself from year to year in somewhat similar fashion and thus that it is possible to measure it. However, it does not follow that conditions will remain unchanged in future periods. Thus, while the seasonal characteristic may have been quite evident in the past, current measurement of seasonally adjusted data is subject to limitations of dossible change in the original conditions. The discovery of a change in seasonal factors normally requires a period of hindsight and to this extent the application of past seasonal factors to current periods must be done cautiously. Seasonal adjustment is therefore a neverending process and the underlying factors have to be kept under continual scrutiny. The process of seasonal adjustment thus has an advantage in the analysis of current data simply because it compels constant scrutiny for possible shifts in the seasonal pattern. Even though it may be impossible to discern the exact natura of this shift, the search for logical reasons for changes in results helps to uncover changes in seasonal factors.

The second assumption involved in the process of seasonal adjustment is that random events will cancel themselves out through time so that they will not have any net effect on seasonal factors. The essence of the problem of seasonal adjustment is to distinguish seasonal characteristics from these random or irregular factors. In the original attempt to define the trend-cycle by means of a twelve month moving average the ratio of the original data to the twelve month centred moving average contain both seasonal and irrecular elements. If those events which we have defined as irregular (i.e. events of which we have some knowledge) are removed from the calculation, then the remaining ratios represent seasonal and random elements. If a sufficient number of observations are used in the computation, then it is assumed that the random element will tend to cancel out, thus leaving a good measure of seasonal.

For our purposes we have defined the minimum period necessary for proper seasonal adjustment to be six years. In some cases six years of data were not available and a number of techniques have been developed to establish proper seasonal patterns in such circumstances. One technique was to extend back the centred moving average free hand for six months at the beginning of the series and forward for six months at the end of the series in order to give an additional observation for each month. (The computation of a moving average loses one halfyear of observations at the beginning and one halfyear at the end of each series.) Another technique was to carry a series back on the basis of some related indicator. An example is the series without jobs and seeking work which was carried back monthly from November, 1952 to 1946, on the trend of unplaced applicants using the quarterly without jobs survey data as a bench mark.

The third assumption underlying seasonal adjustment is that the centred twelve month moving
average is a reasonably good approximation of the trend-cycle thus permitting the estimation of the seasonal element from this trend. As mentioned above, however, the simple twelve month moving average is not a perfect representation of the trendcycle. There is usually a possibility that the twelve month moving average will not trace effectively either the precise timing of the real business cycle nor its exact amplitude from peak to trough. This follows from the fact that each month in each stccessive twelve month moving period gets equal weight ${ }^{1}$. Thus both cyclical movements that occur at a point in time or irregular movements which occur at a point in time will be spread over a full twelve month period. In other words, this moving average tends to be too smooth and because of this characteristic the twelve month moving average has been critized as failing to delineate peaks and troughs clearly enough to portray the exact trendcycle.

There are a number of solutions to the problems involved in the use of a simple twelve-montn moving average. The first possibility is to redraw the moving average free-hand to go deeper into the peaks and troughs, also taking into account the straying of the simple weighted moving average because of an irregular event ${ }^{2}$. This is another aspect of the approximation technique previously described. In such a case, the trend-cycle is given a second approximation before the ratios-to-the moving average are computed.

A second possibility is to remove those ratios which are affected by extreme movements in the moving average, that is to say, the statistician ignores not only those deviations from the moving average which are ia themselves erratic, but also all the deviations which are affected by a distortion in the moving average itself. While this approach causes a considerable loss of information, it is an effective way of handling irregular events when they are not too common.

A third possibility is to change the raw data itself before computing the moving average. In such a case (e.g. the occurrence of a strike) the reported raw data are adjusted upwards by the number of

1. Actually, the weights of a centred twelve-month moving average consist of unit weights for the middle eleven months and half-weights for the two end months. Weights of a more complicated average might be $1,2,3$, 4, $5,6.6,5,4,3,2,1$, a pattern which gives heavier weights to the middle months. A somewhat similar weighting concentration can be obtained by using a 3 of a 4 of a 5 month moving average.
2. This technique is described in the Federal Reserve Bulletin, June, 1941, "Adjustment for Seasonal Varlation", pages 518-528, H.C. Barton, Jt.
people on strike, in effect assuming that no strike occurred. The calculated moving average then portrays a better approximation of the underlying trendcycle. With this information, a good seasonal index may be derived, and this in turn divided into the original raw data, so that the effect of the strike will be shown in the final seasonally adjusted series. This technique has been tested on a large number of employment series, and the results have been promising.

A fourth possibility is to elaborate the method of approximation described earlier in this section. A simple weighted centred moving average is used to derive a seasonally adjusted series, which is then smoothed and used once more in the recalculation of the seasonal indexes; in the recalculation it is not the moving average which is used to compute the ratios, but rather the smoothed first round seasonally adjusted series. This technique of iteration has been used successfully in recent experiments on electronic computers. As can be appreciated, it involves a considerable amount of calculation, and would not prove practicable using hand methods ${ }^{3}$.

## Test of Reliability

Once the seasonal adjustment process has been carried out, a number of tests are applied to judge the accuracy of the seasonal adjustment. First, the sum of the seasonally adjusted data is compared with the sum of the raw data. If the totals afe approximately the same, this is judged to be one test of goodness of the seasonal adjustment. The data are then charted, with each year plotted on top of the previous year in the form of tiers. Any seasonal movement remaining may then be immediately noted and corrections made in the seasonally adjusted series ${ }^{4}$. While there are a number of further calculations which may be made to test the accuracy of the seasonal adjustment depending on the resources available, the conditions set out above appear to be sufficient to attest to the general accuracy of the method ${ }^{5}$.
3. This technique is described more fully in Chapter $X$ of this paper.
4. However, it should be noted that lier charts are a helpful but not a complete check on the adequacy of seasonal adjustment. For example, a tier chart may exhibit residual seasonal but on examination of the devia tion charts the latter are found to be fully accurate. It is the occurrence of irregular events in different months in successive years that gives the impression of residual seasonal.
5. In seasonal adjustment carried out by electronic machines, a number of additional tests are applied. (See Chapter X of this paper.)

## CHAPTER VI

## PROBLEMS OF SEASONALLY ADJUSTING CURRENT DATA

The major limitation inherent in moving averages is the loss of current observations due to centering. Out of this rises the problem of deriving seasonal indexes for use in adjusting current economic data. As a first step the seasonal index for the preceding year may be used. If this gives reasonable results in the light of all known information about the particular series then this procedure is useful. If the results appear unreasonable, that is if sharp breaks in the underlying trend-cycle result or if choppiness becomes apparent in relation to the previous seasonally adjusted series, then further analysis is required. There may be a trend in the previously observed seasonal pattern; that is it may be sloning downward or upward. In such a case an extension of this trend might be used to derive the current seasonal ratio. If this second approach again does not provide reasonable results, it is possible then to extend the moving average of the raw data free hand into the current month and calculate a ratio of the original data to this extrapolated moving average; this approach is more readily adapted to nuarterly than inonthly data. The ratio can then be compared with ratios for preceding years and this comparison helps the statistician to assess the correctness of the current seasonal adjustment. As subsequent data become available and it is possible to extend the moving average,
the basis of these solutions can be checked for reliability and accuracy. It can be seen from the above that a considerable element of judgement is involved in extending the seasonal ratios into the current period.

Judgment must be based on many considerations. Questions such as what is the relationshin betvieen the deviation derived this year and that calculated for last year? Was last year's deviation regarded as unusual and was this a correct interpretation? Should last year's seasonal index and this year's seasonal index be revised in the light of changing circumstances? Does this year's ratio to the moving average reflect an unusual event that is not likely to be repeated in the future?

These questions suggest some of the ways in which the situation may be kept under constant scrutiny. The following chart illustrates this point. It will be noted from the chart that the ratio to the moving average for the current year was considerably above the moving seasonal line as projected. At the same time, the ratio for the previous year was also above the line. While in the previous year this ratio to moving average would have been interpreted as a possible random movement, the evidence furnished by the current year's data casts doubt on

CHART-IV

this initial interpretation. Whether both these ratios to moving averages should be considered as containing a large random element or whether they should be regarded as a change in seasonal pattern can only be determined by examining the relationshi!) to other factors. The statistician must know the nature of the series, the course of events in the past two years, and the forces operating on the basic seqsonal pattern.

All this suggests that if the basic seasonal pattern appears to be changing an effort is made to account for this phenomenon. The procedure followed in such a situation is to exhaust the possibilities of the application of knowledge. If after investigation the statistician is still uncertain of the nature of these movements, the approach then used is to draw the moving seasonal somewhat closer to the deviations than previously but only about half way between the old index and the most recent ratios. If the seasonals are in fact changing this procedure would make the current measure approximate more closely to the seasonal index as finally revised. Alternatively if the movements eventually prove to be random it would minimize the revision that would eventually have to be made.

The rationale of the above approach is that a moving seasonal may continue to move in the same direction as previously, it may stabilize at the present level, or it may change direction. An anallysis of the factors operating upon seasonality in the particular time series may indicate which one of these alternatives lias the highest probability. It was noted earlier that the forces operating on a seasonal are long-run as well as cyclical. Fo the extent that forces are secular, it may be assumed that the index will continue to move in the same direction. There are of course definite limits to the movement of a seasonal, the upper and lower limits being 1,200 and 0 in the case of monthly data, - that is to say, either all or none of the year's activity will take place in one month. If the forces operating on seasonality are likely in the long run to dampen seasonal variation, then all seasonal indexes will tend to move toward 100. Long-run restraints conceivably could cause the moving seasonal to stabilize.

It was pointed out earlier that cyclical forces may also be operating on seasonals, and to this extent it is possible that any seasonal movement might also be altered as business conditions change cyclically.

## CIIAPTER VII

## VARIATIONS IN THE LENGTH OF THE REPORTING PERIOD

Perhaps the most widely used adjustment and one which appears to yield some of the best results is in connection with variations in reporting periods or calendar variation. Variation in the length of the month is one of the most basic of these factors. All other things being equal, output in February would be smaller tian in any other month simply because it is the shortest month of the year. Not only may any economic series differ from month to month within a year purely as a result of calendar variation, but it may al so vary between the same months in different years. If, for example, the factory operates on a five day week, not operating on Saturdays or Sundays, then it is important to know how many Saturdays and Sundays there are in each reporting period. It is possible for a series to vary as much as $10 \%$ in one month purely as a result of the change in number of working days.

The task of the statistician is to ascertain the effect of a varying number of calendar days, to measure them and to remove their influence from time series. The unadjusted data are put on a basis that makes all months equivalent to a daily average. The data are adjusted on this basis before the calculations for seasonal adjustment are carried out. The difficulties encountered in making the adjustment are the practical problems of measuring the effects of calendar variations In the case of production, the situation is reasonably clear in that production is likely to be directly related to the
amount of time put in by workers, and all that would be required is a schedule of the mode of operations within the industry. If a five day week were customary adjustments would be made on that basis.

However, in other time series, for example retail trade, the effect of calendar variation is obscure. If a five or six day working week were customary in retail trade it is by no means certain that sales would vary simply because there would be one day more or less for shopping. Food purchases are probably independent of the number of shopping days in any month. However, it may be that purchases of clothing or durable goods are affected by the number of shopping days. A further complication is the differing importance of various days of the week for shopping purposes. The total value of sales may vary, not in accordance with the total number of shopping days, but rather in accordance with a distribution of the type of days. A Saturday may be of much greater importance for shopping than Mondays. If this were true the best approach would be to weight each day by its relative importance to sales.

The reader will note the complexities involved in this problem. There is the difficulty of establishing whether a working day or calendar adjustment is necessary. If so, the institutional arrangements operating in the area must be ascertained. It may be necessary to obtain statistical evidence of
the importance of different days. While a beginning has been made, a good deal of further research must be undertaken before a completely satisfactory solution can be derived for this particular problem.

At present, calendar day adjustments are made as follows:
(1) In the industrial production series all components are adjusted for working das on the basis of the customary working practices in eqcil industry. This adjustment appears in the raw data published in the Canadian Statistical Review.
(2) All employment series are in effect adjusted for working days before publication of the employment indexes.
(3) Retail trade series are adjusted on the basis of a six day shopping week. All days are given equal weight. The discussion in the previous paragraph indicates the limitations of this approach, but it is considered that the seasonally adjusted series are improved by this procedure.
(4) Merchandise exports and imports are adjusted on the basis of the number of days
worked per week by the customs officials, five and a half days until mid-1953 and five days thereafter. In addition, a number of other adjustments are made. Since on the average, data require two days to reach the final tabulating offices in Ottawa, this delay was taken into account in computing the time period of the month. In addition certain adjustments are made for changes in coding or administrative procedures, particularly for the months of June, 1954 and March and April, 1956. This rather complex procedure proved useful particularly in the import series.

The final test of accuracy was to compare the results of the seasonally adjusted series without the calendar adjustment with those having a calendar adjustment. An improvement was apparent in the import series shown. In the chart below are shown the unadjusted raw data, the seasonally adjusted data without calendar variation and the seasonally adjusted data with calendar variation. The reader will note the improvement effected by the use of the calendar variation adjustment.

The effectiveness of a calendar adjustment of this type can only be judged by comparing the same series seasonally adjusted with and without this
computation. Should there exist a logical relationship between the variation in the calendar and the values established in the time series and should
the calendar adjusted series contain less irregular movement than those without the calendar adjustment, then it was felt that the calendar adjustment should be incorporated into the procedure. This approach is another example of the application of knowledge and logic to time series in preference to purely mechanical procedures.

No special allowance was made for holidays because they fall with the exception of Easter in the same month of each year and would be adjusted for in the normal process of seasonal computation.

## CHAPTER VIII

## VARIATIONS IN SEASONAL PATTERN

## The Shifting Date of Easter

Another set of problems arises when the underlying causes of seasonal variation shift from month to month and are not consistent from year to year. Strictly speaking these movements are not to be classed as seasonal, as seasonality was defined earlier. However to neglect these problems because they do not fall precisely in line with the general notion of seasonals and to treat them as an irregular component is to neglect one of the most fruitful areas of investigation in time series analysis. The problems in this area are calendar variation, Easter, shipping, forestry, farm production and automobile production and sales.

The essence of the problem is that the normal treatment of seasonal variation defines seasonality as a reasonably stable movement from year to year in its pattern, of timing and amplitude. The success of measuring this seasonal factor depends upon minimizing the variation of the ratios of the original data to the moving average for each of the months from year to year. Any unusual variation is immediately suspect and the general approach calls for omitting these aberrations from any computation made. The logic of the adjustments discussed here is quite different. The irregularities are not omitted but are used in the computation because of the information they convey about the composition of the time series and their relationships to some predetermined variable.

For example, as the date of Easter shifts from year to year and at the same time the sale of clothing shifts in much the same manner, then it is useful to measure the difference between the average movement of clothing sales in these months as against the actual movement of clothing sales in the month and relate these differences to the chang. ins date of Easter. If there is a direct relationship, then the seasonal adjustment will be improved. In such a case even thougl the seasonal index will change from year to year, and do so in an irregular manner, this is considered preferable to not making the adjustment. Should the adjustment not be made, the analyst studying the data is faced with the question: "While clothing sales rose seasonally adjusted in March of this year, we know that Easter occurred quite early this year in comparison with previous years. How much of the increase in cloth-
ing purchases was attributable to the early date of Easter and how much to any underlying improvement in business conditions?" Such a question is inevitably raised and the statistician is asked to make an adjustment in any event as an ald to the user.

The metlod of computing the adjustments for the shifting date of Easter is as follows ${ }^{\text { }}$ : The average seasonal variations for the months of March and April are computed. The actual ratio to moving average for each year and the ayerage seasonal ratio are differenced. The differences between the March residual and the April residual for each year are plotted on a chart using the date of Easter as the X -axis. A straight line fitted to these readings becomes the gross correction factor. The correction factor is divided by two and the result subtracted from March and added to April. The correction factor applicable for the date of Easter each year is applied to the average seasonal to give a seasonal index adjusted for the date of Easter.

The logic of the method is•that if movements in the series are affected by the date of Easter, ther the deviations in any specific year will vary from the average of all years in some direct relationship to the date of Easter. For example, should Easter fall in March, then presumably the March sales will increase relatively and the April sales will fall relatively. 'To the extent that this is true, the ratios to moving average for March will be larger than usual and the ratios to moving average for April will be smaller than usual. The difference between the actual ratios and the average ratios for April or March are then related to the early date of Easter. As more observations are obtained there should be a consistent pattern, with the March sales falling relatively more and the April sales increasing relatively more as the date of Easter shifts further into April. The technique outlined above permits a measurement of this relationship.

A number of the retail trade series are affected by the shifting date of Easter. An Easter adjustment is made in the following series: men's and children's clothing, women's clothing, family clothing. shoe stores, drug stores, variety stores and restqurants.

## Other Sudden Shifts in Timing

Similar problems arise in connection with other sudden shifts in the timing of climatic or conventional seasons and solutions like that of the Easter adjustment can be adopted. The obvious examples are the timing of the shipping season, the timing of the winter cutting season in the forests and the timing of the inodel changeover in the automobile industry. It may be that special adjustinents are required in some of the external trade series and in series related to forestry ${ }^{1}$; it is certain that automobile production sales series should be adjusted for the timing of the new model. However, because of lack of data or because further experimentation is required, these special adjustments have not been made to any of the series published in this paper. Special attention is being given to the automobile series and while no definite conclusions have been reached, the reader is wamed that declines registered in the latter nart of the year over the past few years are partly attributable to the shifting date of the changeover. The series related to forestry at present available should also be intrepreted with care.

## Varying Amplitudes Agriculture

A problem of sudden shifts in the seasonal factors arises in the case of agricultural products where the production and shipment of these commodities remains more or less constant in timing from year to year but there are wide variations in amplitude as a result of fortuitous weather conditions. Thus, the wheat crop from the same acreage may vary from one year to the next from perhans 300 million bushels to 600 inillion bushels. In many cases the disposition of these crons is similarly affected, particularly where the commodity cannot be stored. An unusually large tomato crop in any year will be reflected in a large production increase in the harvest season and a correspondingly large decrease in inventories as the crop is disposed of.

The application of some average seasonal technique to this type of phenomenon results in a chonny type of seasonally adjusted series, with large increases showing in the harvest period of some years and large decreases in others. It is not possible to apply a moving seasonal to these series in that the changes from year to year are discrete. The solution in such cases is to compute the seasonal index somewhat analogous to the Easter type of adjustment, which adjusts for varying amplitudes ${ }^{2}$. The seasonal indexes are adjusted each

1. The United States Federal Reserve Board suggests handling problens of this nature by adding together the raw data for the months affected by the changing date of the snowfall, adding together the seasonal indexes for these months and dividing the average seasonal index for these months into the average of the unadjusted data. The seasonally adjusted data for each of the months are identical and the effect of the shifting date of the snowfall is smoothed.
2. See F. E. Croxton and D.J. Cowden, op. cit, Pages 518 to 524.
year for varying amplitude as a regression line is fitted to the seasonal readings and to the deviations from the moving average. No use is made of this technique in any naterial published by the Dominion Burcau of Statistics but experimentation is proceding on some of the agricultural series.

## Discontinuities in Time Series

Time series may show discontinuities in a number of situations, among them the aftermath of war or following the decisions of regulatory bodies and as a reflection of new events ${ }^{3}$. In the analysis of historical data, problems of discontinuity in a series are fairly readily resolved, but in the current measurement of seasonality it is often difficult to arrive at a wholly satisfactory solution. iegardless of the cause of the discontinuity, the best solution in general is to treat the series as two distinct series and to isolate and measure the seasonal factors present in each segment. This presents no difficulty with a long historical series. Four illustrations will serve to show how specific problems of discontinuity have been dealt with in current measurement.
(1) Automobile production and sales in the immediate post-war period, when there was a heavy accumulated demand.
(2) The removal late in 1950 of foreign exchange control board regulations governing the payment of divideuds abroad.
(3) Changes in income tax rates effective at certain dates.
(4) The rapid development of television production after 1952.

In the first example, little or no seasonality was evident in the automobile industry in the immediate post-war period, and the series was left unadjusted for a time. As a seasonal pattern began to re-assert itself, an attempt was made to measure it utilizing previous experience. In the second example, the pattern of dividends paid abroad shifted suddenly and drastically but the seasonal pattern was not obliterated. This time series was broken at 1950 and new seasonal factors estimated for the period thereafter. These factors became increasingly clear with the passage of time but only rough approximations could be made in the first few years. The third example, changes in income tax rates, presented a different problem in that the general seasonal pattern remained stable but it was impos. sible to derive the underlying trend cycle by means of an unweightedmoving average. The simple moving average could not show adequately the timing of the change in tax rates (and the consequent sudden change in the level of collections) with the result that the ratios to moving average did not adequately measure the seasonal variation. The solution adopted was to treat the annual (fiscal year) average as the trend cycle and to calculate the ratios of the raw data to the annual average. This neglected the
3. The problem of measuring seasonality in the presence of new events is often in essence one of weighting, the subject discussed in the following section.
element of growth within the year but the overall results were much improved. The last example concems the rapid development of television production after 1952. This component revealed a seasonal pattern different from that of the rest of the major
industry group, electrical apparatus and supplies, and it was necessary to break the senes at this point and to treat the two components separately in computing seasonal indexes.

## CHAPTER IX

## WEIGHTING AND OTHER TECHNICAL PROBLEMS

Problems of method in the field of seasonal adjustment arise from the possibility that a given answer may be derived either from a direct adjustment of a total or altematively from an adjustment of component parts which are then summed to a total. While the differences in results may not be large, it is only in unusual circumstances that they will be identical. To the extent that there are differences, the problem becomes one of deciding which solution is the better. This problem has a number of ramifications:
(1) What is the best seasonal adjustment for a series? Should it be done at the total level or by the summation of parts?
(2) What is the optimum of detail to use in seasonal adjustment?
(3) Should quarterly adjustments be made independently or should they equal the sum of the component months?
(4) flow is the residual error in the National Accounts affected by internal shifts in weighting?
When a seasonally adjusted series is computed, the original data are divided by the seasonal index. If the total is derived by summation of the various
seasonally adjusted components, this procedure is analogous to deflation by price indexes, the seasonal index being the deflator and seasonally adjusted data the weights. The summation of the seasonally adjusted series then includes all the weights implicit in the movement of the individual components. If the seasonally adjusted total derived by a summation of the parts is divided into the sum of the raw data, the overall implicit seasonal index is currently weighted, the weights being the individual seasonally adjusted components. Only if the weights of the individual seasonally adjusted components remain unchanged over time will the implicit seasonal index of the summed series be identical with that derived from an adjustment of the total. An illustration follows:

Assume a tine series has a constant annual level of 2,400 . Thus, the seasonally adjusted monthly values will be 200. Assuming that the month of January has a constant value of 300 , the seasonal index, will be $\frac{300}{200}=150$. Assume further that the January total consists of 3 items having the following constant values:

Period I

| Item | Unad justed value | Seasonal index | Seasonally adjusted sertes |
| :---: | :---: | :---: | :---: |
|  | $\begin{array}{r} 100 \\ 50 \\ 150 \end{array}$ | $\begin{aligned} & 100 \\ & 200 \\ & 200 \end{aligned}$ | $\begin{array}{r} 100 \\ 25 \\ 75 \end{array}$ |
| Total of items ........................................................ | 300 | 150 | 200 |

Assume now that in period II, the unadjusted iterns vary, although the total remains constant.

This has the effect of changing the weighting of the seasonally adjusted items.

## Period II

The sum of the adjusted series is now different because of shifting weights within the group and the implicit seasonal index is also different. While it appears desirable to take account of compositional shifts in seasonally adjusted series it should be noted that any implicit seasonal index derived after summation of items is currently weighted and may tend to move erratically. For this reason analysis of seasonal indexes per se is more appropriately carried out at the item level wherever the seasonal adjustment has been done in detail.

The advantages of deriving a total as a sum of parts are as follows:
(1) The seasonal pattern is unique for each homogeneous level of detail.
(2) Any unusual event affecting an individual component can be eliminated by applying direct knowledge.
(3) Jhanges in underlying conditions which affect the seasonal pattern can be handled more effectively when components are analysed individually.
(4) Analysis of movements in the total may be facilitated if the seasonally adjusted components are available.
(5) The sum of the parts equals the total thus pernitting reconciliation between the movements in the total and those of the parts.
(6) Weight shifts between individual components are tak en into account.

The approach used by the Dominion Bureau of Statistics in the National Accounts as well as in the selected monthly economic indicators is to derive totals from a sum of the parts where the components are readily available. Thus, totals of retail trade and foreign trade are a summation of the individual groups contained therein. On the other hand, no complete seasonal adjustment is available for all the components of the main industry groups of industrial production and these groups are adjusted at the total level (non-durable manufacturing, durable manufacturing, mining and public utilities).

When it is decided to derive the total from the sum of parts, the statistician must choose the level of detail at which he is able to operate. It will be appreciated that in many series (foreign trade) there are virtually hundreds of series that could be used in summation. The criteria used in such cases were as follows: (1) The groups used should be as homogeneous as possible. so that knowledge could be applied to the series. (2) The level of detail should not be unmanageable. (3) The summation of the seasonally adjusted results should not contain any residual movement ${ }^{1}$.

1. For example, earlier experiments with foreign trade data indicated that after the seasonal movement had been removed from numerous detailed series, a seasonal factor appeared at the total level after summation. This was apparently caused by some underlying seasonal factor, such as shlpping, which manifested itself at the detailed level in a large number of random or irregular events, but which showed up quite clearly in the total. In such cases, it was found that the optimum number of series for seasonal adjustment was considerably smaller than the total amount of data readily available.

It is useful to compare the results of a seasonally adjusted series derived from the summation of its parts with a direct seasonal adjustment of the total. Any differences between the two should be explicable by means of intemal shifts in weighting. When they cannot be so exnlained the individual seasonal adjustinents applied to the component series should be re-examined.

Decisions on sumtnation have also to be made when deriving quarterly totals. If monthly series are available, then it seems worthwhile to derive the quarterly by summation, as is done in the Labour Income series, since adjustments may be more readily made on monthly than on quarterly data. However, many adjustments, working day adjustments for example, which are quite essential in the analysis of month-to-nonth movements, tend to cancel out over a quarter. There is an advantage to be gained by summing monthly data to derive the quarterly, but if quarterly data are all that is desired, a great deal of work nay be saved by applying seasonal factors directly to the quarterly totals. At present the onlynational accounts series derived quarterly from the sum of months is the Labour Income series. However, after further research, other series may be adjusted monthly and summed to quarterly totals.

The problem of weighting and its implications for seasonal adjustment also arises in connection with the summation of seasonally adjusted data to an annual total. As the weighting of the unadjusted series in any year may differ from that implicit in the seasonal indexes due to irregular elements, the sum of the seasonally adjusted data will diverge from that of the raw data. Only when the weighting is identical ${ }^{2}$ as between the seasonal index and the raw data will the two sums be equivalent. In such a case, the final seasonally adjusted result contains no irregular or random elements and is represented by a smooth curve. This is a very special situation (see Model I). Normally, there is some difference between the annual sum of the seasonally adjusted data and the annual sum of the unadjusted data (see Model II). However one of the tests of goodness of seasonal adjustment is for the two series to sum to approximately the same total ${ }^{3}$. While it is recognized that such differences exist, no specific adjustment is usually made to equate the seasonally adjusted material to that of the unadjusted material. However, in dealing with quarterly National Accounts, for reasons of consistency, the seasonally adjusted components are further adjusted to the annual level of the unadjusted material. The differences are prorated over the values. It should be noted that this procedure mak es for a slight discontinuity between years. However, the discontinuity is slight and it is considered to be justified by the need to maintain consistency with the unadjusted data.
2. It is possible that shifts in weighting may be offsetting and the sums of the unadjusted and adjusted series match exactly.
3. Bums and Mitchell in "The Measuring Business Cycles', page 42 , suggest a tolerance of 10 per cent between the sum of the seasonally adjusted and that of the unadjusted. In D.B.S. experience, most of the differences are in the range of 2 to 3 per cent and 10 per cent is unusual.

Model I

| Raw | Seasonal index | Seasonally adjusted |
| :---: | :---: | :---: |
|  |  |  |
| 150 | 50 | 100 |
| 100 | 150 | 100 |
| 100 | 100 | 100 |
| 400 | $\frac{100}{400}$ | 400 |

Model II

| Raw | Seasonal index | Seasonally adjusted |
| :---: | :---: | :---: |
|  |  |  |
| 45 | 50 | 90 |
| 155 | 150 | 103 |
| 100 | 100 | 100 |
| $\frac{100}{400}$ | $\frac{100}{393}$ |  |

An interesting aspect of the weighting problem arises in the seasonal adjustment of the National Accounts. Dwing to shifts in the composition of iross National Product and rxpenditure, it is possible for the national accounts to contain some
residual error after seasonal adjustment, even though the components themselves have been properly adjusted. The following example illustrates how this may arise.

Period I

| Gross national product |  |  |  | Gross national expenditure |  |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
|  | Raw | Seasonal index | Seasonally adjusted |  | Raw | Seasonal index | Seasonally adj usted |
| Wages and salaries ............ | 1,000 | 50 | 2,000 |  |  | 50 | 2,000 |
| Corporation profits ............. | 1,000 | 100 | 1,000 | Government expenditure .... | $1,000$ | 100 | 1,000 |
| Gross national product........ | 2,000 |  | 3,000 | Gross national expenditure | 2, 000 |  | 3,000 |

## Period II

|  |  |  |  |  |  |  |  |
| :--- | ---: | ---: | ---: | :--- | :--- | ---: | ---: |
| Wages and salaries ............. | 1,500 | 50 | 3,000 | Consumer expenditure....... | 1,000 | 50 | 2,000 |
| Corporation profits ........... | 500 | 100 | 500 | Government' expenditure $\ldots \ldots$ | 1,000 | 100 | 1,000 |
| Gross national product $\ldots \ldots . .$. | 2,000 |  | 3,500 | Gross national expenditure | 2,000 |  | 3,000 |

It is amparent that in Period I no difficulty arises from the process of seasonal adjustinent, seasonally adjusted Gross National Product being equal to seasonally adjusted iross National Expenditure. I Yowever, in Period II, with a drastic shift in the composition of Gross National Product. the seasonally adjusted total is no longer identical
with Gross National Fxpenditure and there is no reason why it should be identical. Indeed the two totals would be identical only if the implicit weightings of the various seasonal indexes on both sides of the accounts were to remain the same, or to change in the same proportions. In this example, where wages and salaries increased and corporation
profits fell, it would have been necessary for consumer expenditure and government expenditure to have moved in precisely the same fashion as the Gross National Product components just mentioned. Such parallel inovements would occur only in unusual circumstances. Although any imbalance between the accounts after seasonal adjustment, purely as a result of weighting, may be quite sinall, it is worthwhile noting that it does occur.

## Other Problems

There are some series which, as a result of their peculiar characteristics, require a treatment slightly different from the usual approach. For example, where negative items appear in a series, as in inventory change, or where the data approach zero, then the application of the ratio to moving average technique becomes exceedingly difficult or even impossible. The approach adopted in such cases is to use an additive rather than a multiplicative type of seasonal factor, that is the seasonals are computed in absolute amounts rather than as ratios or percentages of the total. The procedures followed are analogous to those previously outlined, except that the ratio to moving average is
replaced by the absolute difference between the original data and the moving average, and the seasonal factor, when derived, is subtracted from the original data rather than being divided into it. This technique has been successfully applied to the series of inventory change in the quarterly National Accounts. Should there be a growth element in the series, so that a constant absolute ainount proves inapplicable, then the treatment proposed is to break the series every few years, and change the seasonal factor, or, alternatively, to adopt a moving seasonal factor.

Another difficult problem arises when a large irregular element appears during a seasonally low period. The application of the normal seasonal index to the data magnifies the irregular element out of all proportion to its actual impact. A solution to this problem has been suggested ${ }^{1}$. The procedure is to (1) multiply the moving average by the seasonal index, (2) subtract this product from the original data, (3) add this difference to the moving average. Step (1) estimates the unadjusted data, free from the irregular component. Step (2) derives the irregular component. Step (3) yields the trendcycle plus the irregular, without laving magnified the irregular by the seasonal index.

## CHAPTER X

## FUTURE DEVELOPMENTS

The program for the future will develop along several lines. It is planned to expand the number of series to be seasonally adjusted, as available resources permit. More research will be done on problems of calendar adjustment, working day adjustment, and related matters, as discussed in a previous section. Techniques to overcome some of the limitations of an unweighted moving average are to be evolved, with the possibility that many of the judmatical decisions involved in the removal of extreme items will no longer be necessary.

The use of high speed electronic computors opens up new possibilities in the development of seasonally adjusted time series. In the past, the high cost of processing by hand put limits to the number of series that could be handled and hampered the adoption of more elaborate techniques. Electronic machines are well suited to the process of seasonal adjustment. In seasonal adjustment, a large number of calculations are performed on a relatively small amount of data and electronic machines perform best under these conditions. The judgment decisions which are made in the normal procedure of seasonal adjustment, such as the elimination of extreme items, can be elaborated fully, and specific instructions given to the machine for handing any given possibility. The ability to store previously computed results and to perform operations in sequence based upon specific instructions
makes possible the process of seasonal adjustment with a great deal of accuracy. Finally, the speed of operation of the machine is such as to make feasible and practicahle calculations which, while marginal in result, are nevertheless an improvement. Many series have been seasonally adjusted by electronic machines in the United States, and future development in this field appears certain. The Dominion Bureau of Statistics is experimenting with this technique, and as experimentation continues it is possible that Canadian data will be processed in this manner.

A brief outline of the seasonal adjustment technique on electronic machines follows so that the reader may appreciate the significance of this development and understand how many of the judgment decisions are handled.

The general approach on electronic machines is one of relteration. A preliminary seasonally adjusted series, derived in much the standard manner. is smoothed by a weighted moving average, giving a much more sensitive indicator of the underlying trend and cycle, with the erratic elements removed. This result is then used as the basis of a second

[^2]round of calculations. The ratios of the original data to the smoothed seasonally adjusted series are calculated. These ratios are then used to compute a moving seasonal. The irregular elements are removed by a formula which gives much less weight to those ratios which are outside the range of a given tolerance. It will be noted that a great many of the judgment decisions made by the statistician in the normal process of seasonal adjustment are based upon the limitations of the moving average in adequately describing the underlying trend and cycle. The procedure adopted in the use of electronic machines solves most of these problems by calculating a better estimate of the trend-cycle with the irregular component removed. Results achieved by the procedure outlined, on testing, compare favourably with the best hand methods.

Some additional features of seasonal adjustment by electronic machines might be mentioned. Ease and speed of calculation makes possible many more computations than can be carried out by laborious and costly hand methods. For example, ratios of one month with the average of the preceding and following months can be calculated to establish whether seasonality exists in the raw data and to determine whether seasonality has been completely removed from the seasonally adjusted data. The relationship of the seasonally adjusted series to a series obtained by a further smoothing by a weighted moving average gives a measurement of the irregular component. Month-to-month changes in the smoothed seasonally adjusted series can be averaged to give a measurement of the average am-
plitude of the underlying trend-cycle. Comparisons can be made to derive the average seasonal in a month-to-month change. The relationships between irregular movements, cyclical movements and seasonal movements gives an additional tool for use in the analysis of time series. For example, a series having a small irregular movement compared with its average trend-cyclical change can be used more confidently than a series with a large irregular movement, in the interpretation of current movements of time series. Series that have been adjusted for working days or some other calendar variation may be compared with the same series without the additional adjustment. If the adjustment for working days is effective, it will reduce the irregular component in the series, and this can be determined quickly on an electronic computer. At the same time, the approach suggested previously for improving seasonally adjusted series, that is the application of specific knowledge to time series, generally requires some type of correlation technique (e.g. easter adjustment). This involves a considerable amount of calculation, and the use of electronic machines will permit more extensive calculations to be made.

The reader should note that the developments just outlined are an elaboration of the principles that have been established by the better type of hand seasonal adjustment. An understanding of these principles is essential in appreciating the limitations and uses of material developed wholly by electronic machines, as well as its future possibilities.

1. This series becane availaole on a monthly basis as of November 1952. Prior to this date only quarterly surveys were available. To obtain an unadjusted series that is sufficiently long for developing a seasonal pattern, interpolation petween these quarterly survey dates was inade on the basis of the Live Applicants for Employnent series.

[^0]:    1. The reader should note that the removal of seasonal variation from a time serles does not indicate how the series would have moved had there been no seasonal variation, Rather it shows more clearly the trend-cycle, abstracting from seasonal variation. The process is somewhat analogous to price deflation, whereby volume comparisons can be made though these comparisons do not show what would have happened in the absence of price change.
[^1]:    1. A five term moving average would be preferable but many series are not long enough to allow for it. Difficulties associated with a three term average can be taken into account by statistician.
[^2]:    1. See A.F., Burns and W.C. Mitchell, "Measuring Buslness Cycles", National Bureau of Economic Research, New York, page 49.
[^3]:    1. Compiled from data which relate to the last pay period of the preceding month.
[^4]:    1. This series is in process of being revised.
[^5]:    1. Seasonal adjustment computed by Central Mortgage and Housing Corporation.
[^6]:    1. Seasonal adjustment computed by Central Mortgage and Housing Corporation.
