## SUMMARY

---

The purpose of the study was to ascertain to what extent five, ten, fifteen and twenty-five-year averages of the annual mean daily floods approach forty-year averages and to investigate trends in these short-term statistics.

The short-term averages oscillate about the forty-year mean, seldom becoming, statistically speaking, significantly different from the forty-year mean. The ten-year averages show a declining tendency through the 1930's and 1940's with an increase in the 1950's and a slight decrease in the 1960's.

Some streams show much less variation in averages than others, and this appears to be related to location rather than stream size.

## INTRODUCTION

The object of this study was to ascertain to what extent five, ten, fifteen and twenty-five year averages of annual mean daily floods approach forty-year averages and to investigate trends in these short-term statistics.

For this study, the annual maximum mean daily floods for twenty-six streams in British Columbia are analyzed in five, ten, fifteen, twenty-five and forty-year periods from 1930 to 1969. If a short period can be found in which the averages are statistically similar to the long-term average, then this period may be of value in regionalization studies. If trends are found, these will be of value in assessing the records of other streams for which short periods of record are available.

## PROCEDURE

The annual maximum mean daily floods for this study were provided by a report entitled, "*Magnitude of Floods in British Columbia*". As these data have three significant figures, results have been rounded to three figures. The majority of stations selected for this study were stations recording natural flow except as noted in Table 1. The locations of the stations are shown in Figure 1.

The forty-year period from 1930 to 1969 was the longest period with the largest number of stations having continuous records. Also it was desirable to compare the averages on a common basis, i.e., a common forty-year period. At six stations, one or two years were missing. In these cases, 1929 or 1970 data were added to bring the length of record to forty years. (See Table 1).

For Station 08LF051, Thompson River near Spences Bridge, the five-year period, 1925-1929, was substituted for 1930-1934 since two consecutive years, 1932-1933, were missing.

A computer program listed in Appendix 1 was used to calculate the average, standard deviation, coefficient of variation and the maximum and minimum floods for five, ten, fifteen, twenty-five and forty-year periods, with average referring to the arithmetic average. In addition, the ratios of the short-term averages to the long-term, i.e., forty-year averages, were produced. The results for the ratios of ten-year average to forty-year average are shown in Figures 2 to 5. The skew calculation should be disregarded in this study, as forty years is too short an interval to produce a meaningful value. (See Appendix 3). The program was written in Fortran IV and run on an IBM 360.

A criterion was required to establish whether or not the short-term and the long-term averages are statistically similar. The development of the criterion is provided in Appendix 2. At a 5 per cent level of significance, the ten-year and forty-year average floods were similar if,

$$0.90 \leq RAFL \leq 1.10.$$

RAFL is the ratio of the short-term average to the long-term average. While the twenty-five-year and forty-year averages were similar if,

$$0.93 \leq \text{RAFL} \leq 1.07.$$

## RESULTS

---

A graphical demonstration of selected results of the study is shown in Figures 2 to 12. In Figures 2 to 5, ten-year averages are selected because they demonstrate the essential trends. These figures are intended for demonstration of each stream's time variation, not for stream-to-stream comparison. The statistics shown in Figures 6 to 12 are selected to represent the general areas of the Province covered by the study.

The numerical values for all the stations in the study are presented in Tables 2 to 27. The units of floods are cfs.

For the Columbia River at Nicholson the forty-year, 1930-1969, average (15200) was compared with the sixty-seven-year, 1903-1969, average (15500) as a check on the forty-year period, 1930-1969. These values are statistically similar. 1930-1969 appears to be a reasonable base period, i.e., representative of the flow recording history in British Columbia.

### (a) Five-Year Averages

As shown in Figures 6 to 12, there is more variation in five-year averages than in longer-term averages; in general, for most streams, 1960-1964 and 1965-1969 averages are closest to the long-term averages. The general pattern is decreasing averages through the '30's and early '40's with increases in the late '40's and '50's and decreases again in the '60's. Considerable variation in five-year average floods is shown even for large streams; for example, the Fraser River at Hope, Figure 9.

### (b) Ten-Year Averages

The ratios of the ten-year average to the forty-year average, RAFL, are plotted in Figures 2 to 5, for each stream in decades 1930-1939, 1940-1949, 1950-1959 and

1960-1969. The limits within which the ten-year average may be considered statistically similar to the long-term average are indicated by dashed lines. In the decades 1930-1939 and 1940-1949 no stream has significantly higher than average flood and several are significantly lower. In the decades 1950-1959 and 1960-1969 no stream has significantly lower-than-average flood and of the four decades, 1960-1969 has most streams with averages similar to the forty-year average flood.

(c) Fifteen-Year Averages

Three fifteen-year periods were considered: 1930-1944, 1945-1959 and 1955-1969. The 1930-1944 averages are all lower than the forty-year average and the 1945-1959 and 1955-1969 averages are all higher.

(d) Twenty-Five-Year Averages

The twenty-five-year averages for 1930-1954 are all lower than, but in general, statistically similar to the forty-year average, according to the criterion developed in Appendix 2. Only the Columbia at Nicholson, Bull at Wardner and Okanagan at Okanagan Falls have significantly lower values and the Okanagan is highly regulated. Further, the twenty-five and forty-year values of standard deviation and maximum and minimum floods are similar. Therefore the information content in this twenty-five-year record and the forty-year record appears similar, at least for the statistics over the period in the study.

However, the twenty-five-year averages for 1945-1969 show fourteen streams with averages significantly greater than the forty-year average. This period is apparently largely controlled or weighted by the higher-than-average floods in the late '40's and '50's. The information content in this twenty-five-year period appears different than that of the forty-year period.

To investigate the information content of twenty-five and forty-year statistics in an analytical manner, Figure 13 was plotted. The analysis behind Figure 13 is contained in "Accuracy of Streamflow Characteristics" by Clayton H. Hardison, 1969. In general, the relative standard error of the mean is reduced by one per cent when the record is extended from twenty-five to forty years with a coefficient of variation of 0.25. This is shown for two streams, the Bull River near Wardner, Figure 14, reduction in relative standard error 1.5%, CV = 0.30; and Lillooet River near Pemberton, Figure 15, reduction in standard error 0.5%, CV = 0.21. The relative standard error of the mean is given by:

$$\frac{100}{\bar{x} * \sqrt{\frac{SD}{N}}}$$

in which  $\bar{x}$  is the mean, SD is the standard deviation and N is the number of events. However, care must be taken in the selection of the twenty-five-year period, as witnessed by the results of this study.

Figure 13 shows that the higher the coefficient of variation the longer the record must be to achieve a given relative standard error.

The streams of coastal and northern areas of the Province are not represented in this study and results should not be extrapolated to these areas. The streams that have been covered have a similar time variation in average values for different geographical areas as witnessed in Figures 2 to 5. Some streams, such as the Lillooet near Pemberton, the Bulkley at Quick and the Chilko at Redstone, show relatively little variation in average flood when compared with streams in the south-eastern area.

## APPENDIX 2

### DEVELOPMENT OF CRITERION FOR STATISTICAL

#### SIMILARITY OF AVERAGE VALUES

By the Central Limit Theorem, if a random variable  $x$  has a distribution with mean  $\mu$  and standard deviation  $\sigma$  for which the first two moments exist, then  $t = (\bar{x} - \mu) * \frac{1}{\sqrt{n}}$  has a distribution which approaches the standard normal distribution as  $n$  the sample size becomes infinite. A standard normal distribution is a normal distribution with mean = 0. and standard deviation = 1.

The following statistical criterion is developed under the assumptions that:

1. Flow is a random variable with a distribution for which the first two moments exist;
2. The forty-year average flow and standard deviation approximate  $\mu$  and  $\sigma$ ;
3.  $n = 10$  and  $n = 25$  are sufficiently large samples for the Central Limit Theorem to apply.

For a 5% level of significance  $t = (\bar{x} - \mu) * \frac{1}{\sqrt{n}}$  must be less than or equal to 1.64 for statistical similarity of  $\bar{x}$  and  $\mu$ . In this case,  $\bar{x}$  is the sample mean,  $\mu$  is the population mean,  $\sigma$  is the variance of population and  $n$  is the size of the sample.

Let  $\mu$  be the forty-year average  
 $\bar{x}$  be the short-term average, i.e.,  
 ten-year average or  
 twenty-five-year average  
 $\sigma$  be the forty-year standard deviation  
 CV be the coefficient of variation,  $\frac{\sigma}{\mu}$

$$\text{RAFL} = \frac{\bar{x}}{\mu}$$

$$\begin{aligned}
 t &= \left| \frac{\bar{x} - \mu}{\sigma} \right| * \sqrt{n} \leq 1.64 \\
 &= \left| \frac{\frac{\bar{x}}{\mu} - 1}{\frac{\sigma}{\mu}} \right| * \sqrt{n} \leq 1.64 \\
 &= \left| \text{RAFL} - 1 \right| \leq \frac{1.64}{\sqrt{n}} * \text{CV}
 \end{aligned}$$

CV is 0.24, an average value for the streams considered in this study, so with  $n = 10$

$$\begin{aligned}
 \left| \text{RAFL} - 1 \right| &\leq 0.10 \\
 \text{or } 0.90 &\leq \text{RAFL} \leq 1.10
 \end{aligned}$$

For  $n = 25$ ,  $0.93 \leq \text{RAFL} \leq 1.07$

## APPENDIX 3

### REPORT ON RESULTS FROM A COMPUTER PROGRAM

#### TO SAMPLE FLOW SEQUENCES

##### Object:

To examine the effects of sample size on the average, standard deviation, and skew coefficient of a sample from a known non-normal population.

##### Procedure:

To generate a known non-normal population, a density curve of flood peak discharge was adopted from Methods of Flow Frequency Analysis - Notes on Hydrologic Activities Bulletin No.13, April 1966. This curve, when carefully traced on graph paper, provided the relative frequencies of various peak flows. Flows in the population were arbitrarily taken to range from 25 CFS to 1600 CFS in 25 CFS increments, with the size of the population taken to be 1000.

The number of each of the flows was found by multiplying the relative frequency of that flow by 1000. Then this number was distributed randomly in the 1000 occurrence array. For example, for a flow of 25 CFS,  $1000 \times 0.003$  or three occurrences were located at positions 319, 414 and 947. The position was found by the generation of a random number between 0. and 1. from a uniform distribution, University of British Columbia, Random Number Generators. This number was multiplied by 1000 and if the location so generated was found to be empty, the flow was entered. If the location was not empty, the procedure was repeated until an empty position was found.

When the array was complete, 30 samples of each of 25, 50, 75 and 100 consecutive occurrences were drawn and the average, standard distribution and skew coefficient were calculated. The draws were performed by generating a random number between 1 and 1000, as previously described. This number provided the entry point for the sample.

The routine for calculation of average, standard deviation and skew coefficient was checked on data from Formulae and Tables for Computing and Plotting Drought Frequency Curves, Technical Bulletin No.8, Inland Waters Branch, 1967.

Results:

The results of the samples are summarized in the following table:

Sampling Period	No. of Samples	Avg. Flow	Max. Flow	Min. Flow	Avg. S.D.	Max. S.D.	Min. S.D.	Avg. Skew	Max. Skew	Min. Skew
25	30	391	501	313	245	323	155	0.84	1.34	0.24
50	30	393	464	320	249	313	188	0.99	1.53	0.37
75	30	398	457	339	254	295	210	0.96	1.44	0.50
100	30	397	446	347	248	294	207	0.94	1.23	0.53
Population	-	397			255			1.02		

This table indicates that:

1. The skew coefficient cannot be estimated reliably from samples of 100 years or less;
2. Increasing the length of the sampling period does decrease the range from maximum to minimum value of the statistical parameters with the decrease being comparatively low from 75 to 100. On this basis a 75-year or 75-occurrence sample would appear to contain almost as much information as the 100-year sample from the point of view of estimating average and standard deviation.

However, these are results for a specific case and statistical tests have not been performed to decide whether the 100-year statistics are statistically similar to the 75-year statistics.

## EXPLANATION OF THE QUANTITIES IN THE TABLES

---

1. The Years of Record are the number of events (N) in the Period of Record.
2. The Average of Annual Mean Daily Floods is the arithmetic average, given by,

$$\frac{\sum_{i=1}^N \text{FLOOD } i}{N},$$

where FLOOD is the maximum mean daily flow of the  $i$ th year. As the units of the individual floods are cubic feet per second (cfs), the units of Average of Annual Mean Daily Floods are also cfs.

3. The Ratio to 40 Year Average refers to the short-term average - for example, a particular 5-year average flood - divided by the 40-year average flood.
4. The Standard Deviation over a period is equal to

$$\sqrt{\frac{\sum_{i=1}^N (\text{FLOOD } i - \text{AVERAGE FLOOD})^2}{(N-1)}}$$

Where the AVERAGE FLOOD is the average over the period of record under consideration. The units are cfs.

5. The Coefficient of Variation is the ratio of the standard deviation to the average. This ratio is dimensionless.
6. For the period under consideration the highest and lowest maximum mean daily flow are shown. The units are cfs.
7. Statistical similarity is determined on the basis of the criteria developed in Appendix 2.

	1946-1970	21500	1.03*	4880	0.227	31600	13200
40	1931-1970	20800	1.00	5310	0.255	31600	10300

\* Statistically similar to 40-year average

Drainage Area: 2800 square miles

## FIGURES

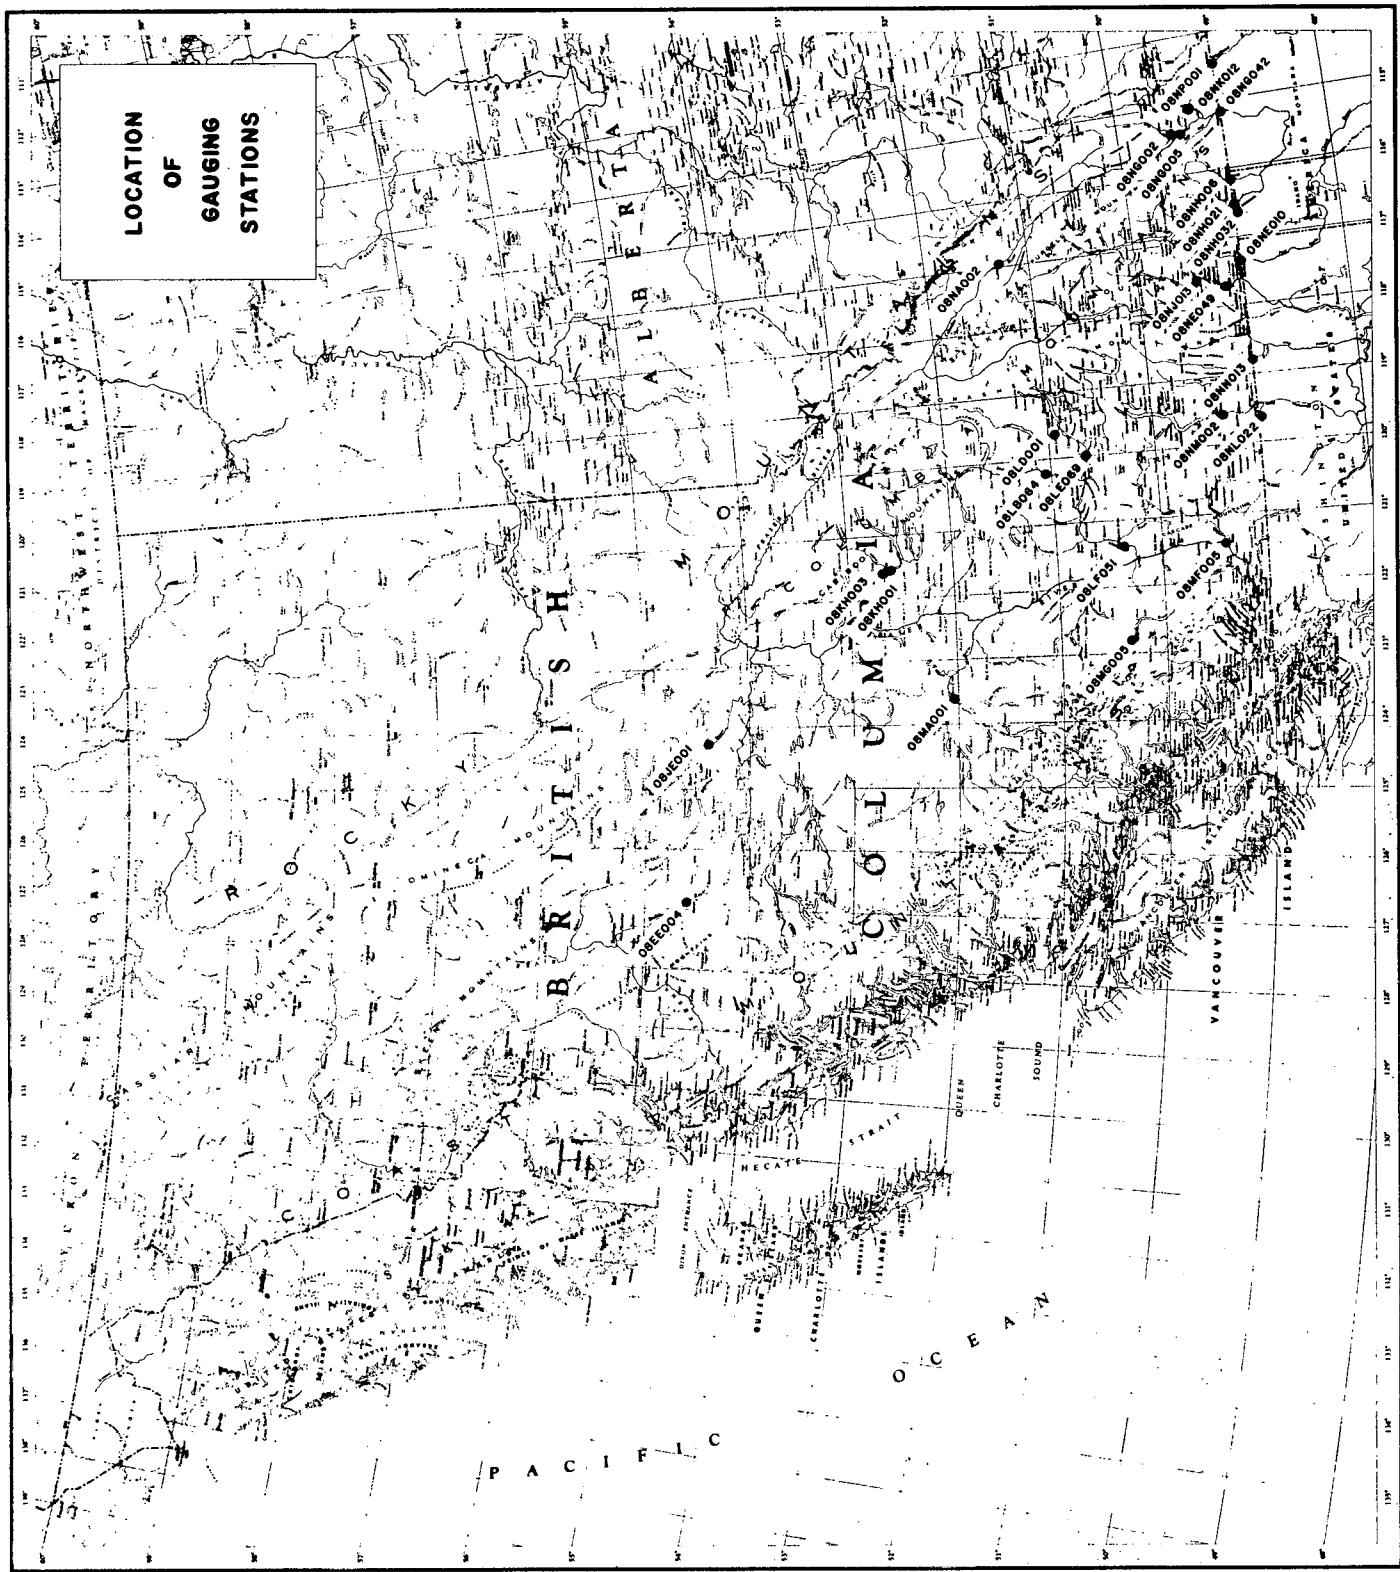

1. Map of British Columbia indicating locations of Stations used in the Study.

Ratios of Ten-Year Average Flood to Forty-Year Average for:

2. 1930 - 1939
3. 1940 - 1949
4. 1950 - 1959
5. 1960 - 1969

Averages and Standard Deviations of Annual Mean Daily Floods for:

6. 08NE049 Columbia River at Birchbank
7. 08NG042 Kootenay River at Newgate
8. 08NG002 Bull River near Wardner
9. 08MF005 Fraser River at Hope
10. 08LB064 North Thompson River at McLure
11. 08MG005 Lillooet River near Pemberton
12. 08EE004 Bulkley River at Quick
13. Relative Standard Error of Average and Standard Deviation as a Function of Length of Record and Coefficient of Variation.
14. Relative Standard Error of Estimate of the Mean as a Function of Length of Record for Station No. 08NG002 - Bull River near Wardner.
15. Relative Standard Error of Estimate of the Mean as a Function of Length of Record for Station No. 08MG005 - Lillooet River at Pemberton.
