Abstract

The report outlines the distribution of permafrost and gas hydrates as determined from conventional well logs run in 151 wells in the Arctic Islands. Ice-bearing permafrost is interpreted to exist on land to depths ranging from 131 m to 860 m. Although it is also observed in the offshore the data is inadequate to map the occurrence accurately. Natural gas hydrates are interpreted in 90 of the 151 wells to depths of 1923 m.

Résumé

Ce rapport trace la distribution du pergélisol et des hydrates de gaz naturel, telle qu'indiquer par les diagraphies classiques de 151 forages dans les Iles de l'Arctique. L'interprétation des diagraphies à terre révèle l'existence du pergélisol portant de la glace jusqu'à des profondeurs variant entre 131 et 860 m. Quoique ce pergélisol a été également détecté sous la mer, les données ne sont pas suffisantes pour établir sa distribution avec précision. L'interprétation révèle aussi la présence d'hydrates de gaz naturel dans 90 des 151 forages, à des profondeurs allant jusqu'à 1923 m.

1.0

INTRODUCTION

Hardy Associates (1978) Ltd. was retained by Supply and Services Canada, on behalf of the Earth Physics Branch (Energy, Mines and Resources), to undertake a "Study of Well Logs in the Arctic Islands to Outline Permafrost Thickness and/or Gas Hydrate Occurrence" Authorization to proceed with the study was received, under DSS Contract No 27SQ.23225-1035, in September, 1983.

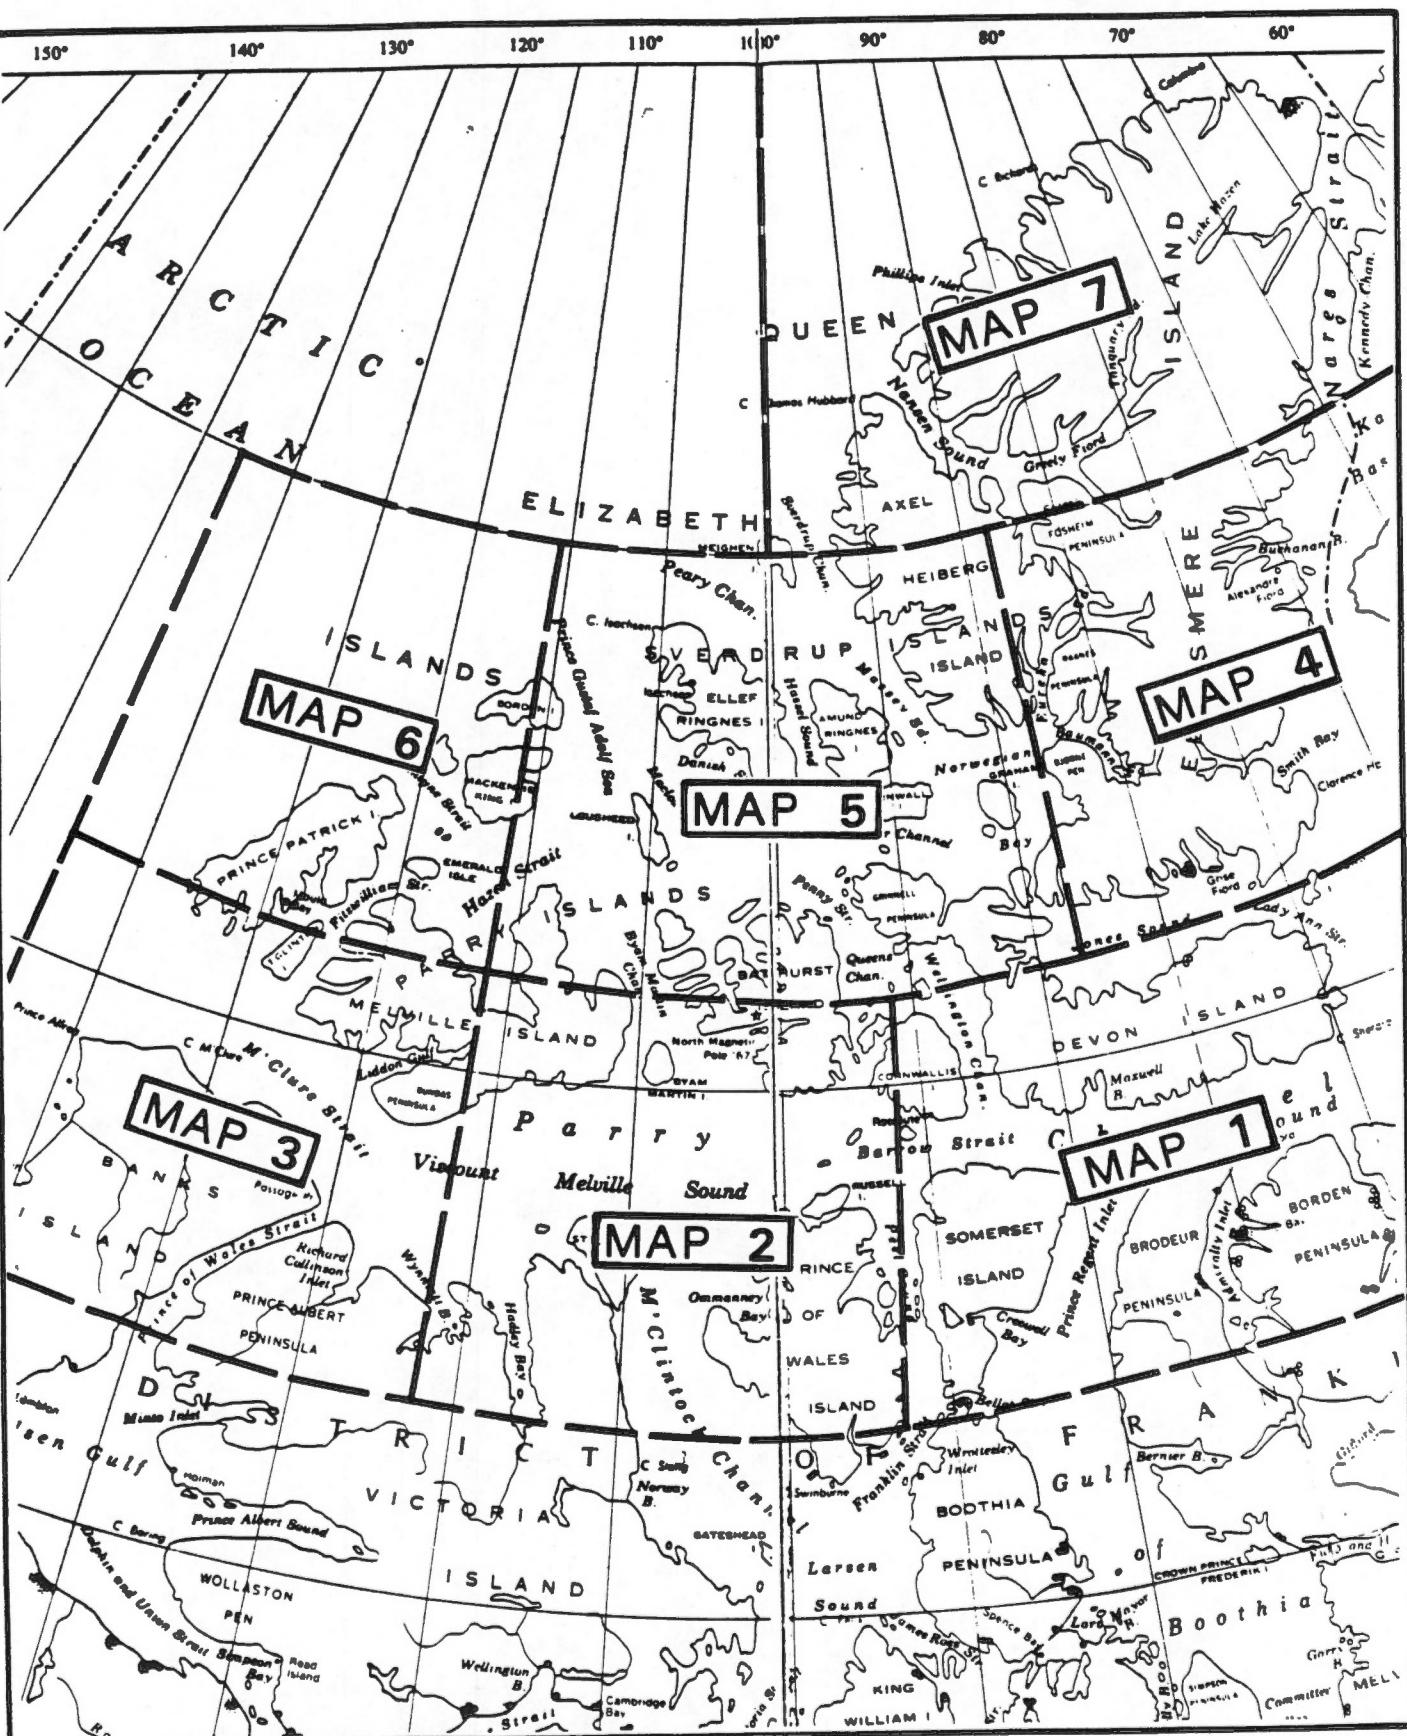

1.1

SCOPE OF STUDY

Since the early 1960's, a large number of wells have been drilled in the Canadian Arctic Islands, in connection with petroleum exploration. These are located throughout the islands but have been concentrated in two main exploration areas: the Sverdup Basin and Parry Island Fold Belt. Almost all of the wells, both on and offshore, have encountered permafrost and, in a number of instances, the presence of natural gas (methane) hydrates has been either suspected or confirmed.

The overall objective of the present study was to "outline permafrost thickness and/or gas hydrate occurrence" in the area, through a comprehensive examination and evaluation of downhole geophysical (petrophysical) logs.

The study area, comprising the portion of the Arctic Islands that is located between latitudes 72°N and 90°N and longitudes 80°W and 126°W, is shown on Figure 1. For ease of discussion and presentation in the report, it has been subdivided into seven sections (also shown on Figure 1), that each correspond

to an International Map of the World (1:1 million scale) map sheet. In all, some 151 wells have been included in the study, each of which had "off-confidential" status as of July 31, 1983. A listing is presented on Table 1.

It is intended that the results of the study should complement data obtained to date from the Arctic Islands by the Earth Physics Branch, with respect to permafrost thickness and distribution and the occurrence of hydrate-prone areas.

1.2 TERMS OF REFERENCE

Detailed terms of reference were established in the request for proposal and in our proposal dated August 1983, as follows:

- i) Examine downhole logs of all exploratory wells, both on and offshore, that have passed the confidential period from the Arctic Islands area, to a depth of 2000 m.
- ii) Review reports on similar studies and survey relevant literature to evaluate past practice and apply the best of currently accepted criteria to all available logs on each well. The major logs to be consulted are crystal cable, sonic, resistivity, induction, self-potential and caliper logs.
- iii) Produce a brief report, outlining the techniques used to define permafrost and hydrates and providing a review of the results obtained through concise tables and maps.

1.3 METHODOLOGY

In order to achieve the project objectives, the assignment was carried out in stages.

Firstly, available sources of published and unpublished information, pertinent to the requirements of the study, were reviewed. Reference was made to three main types of data source:

- i) Earth Physics Branch (E.P.B.) publications, concerning the distributions of ground temperatures, permafrost and hydrate-prone areas.
- ii) Published interpretations of permafrost and hydrate occurrence in the Arctic Islands, based on downhole well logs, and those released by the operators.
- iii) Published interpretations for other areas, primarily the Mackenzie Delta - Beaufort Sea area and Alaska.

Throughout, emphasis was placed on gaining an overall impression of permafrost and hydrate distribution and on identifying the downhole logging techniques that have proven to be of value in the past.

Based on the literature review and extensive previous petrophysical logging experience, diagnostic criteria were then developed for identifying permafrost thickness and hydrate occurrence using the downhole petrophysical logs. The procedures and criteria were refined and improved as the

initial stages of log interpretation proceeded. Section 2.0 provides a detailed description.

The log interpretation was carried out in three stages. Firstly, wells to be included in the study were selected (by reference to D.I.A.N.D. (1980) and required downhole logs obtained. The logs from wells for which interpretations of permafrost and/or hydrate occurrence have already been published, or released by the operators, were then examined. About 50 wells fell into this category. Of this group, data on the wells for which precise temperature surveys are available (carried out either by the Earth Physics Branch (E.P.B.) or industry) were reviewed initially, and then those for which temperature data are not available. In each case, all available logs were examined, so as to provide either support for the published interpretation or, if necessary, a revised or alternative interpretation. Finally, the logs of wells for which interpretations have not been made available previously were examined. Using the diagnostic criteria developed, permafrost thickness and/or hydrate occurrence were "picked". Wherever possible, wells with existing temperature data were examined first.

Preparation and submission of this report constituted the final study task.

1.4 PROJECT TEAM

The assignment was carried out by Hardy Associates (1978) Ltd., Calgary, Alberta, with petrophysical logging expertise provided, on a sub-contract basis, by Petrophysical Consultants International Ltd. Key personnel were as follows.

Dr. J.F. Nixon, P.Eng., of Hardy Associates was project manager, responsible for overall supervision of the assignment and internal review.

Mr. G.E. Dawson-Grove, P.Eng., P.Geol., of Petrophysical Consultants International, developed the diagnostic criteria and carried out the petrophysical log interpretation.

Mr. I. Jones, M.Sc., P.Geol., of Hardy Associates supervised the study on a day-to-day basis, and was responsible for the review of existing literature and final report preparation.

1.5 ACKNOWLEDGEMENTS

Petrophysical logs for the majority of the Arctic Island wells were obtained on a commercial basis. We are grateful, in addition, to the following, for assistance in obtaining the remaining data:

Mr. L. Bruch, M.J. Systems, who arranged for the timely use of a microfiche reader-printer.

Messrs. J. Greenslade and J. Thompson of Panarctic Oils Ltd., who arranged for logs of recently off-confidential Panarctic wells, mud gas logs, and crystal cable data to be made available.

2.0 DIAGNOSTIC CRITERIA

This section describes the criteria adopted to determine permafrost thickness and the occurrence of natural gas hydrates, based on analysis of downhole well logs. Following

a review of pertinent definitions and concepts, the response of petrophysical and other logs to the occurrence of the two phenomena is outlined, based on theoretical considerations and on a review of the literature. With this basis, Sections 2.4 and 2.5 detail the diagnostic techniques developed, and improved upon, in this study, to determine permafrost thicknesses and natural gas hydrate occurrence in the Arctic Islands. A brief summary is presented in Section 2.6.

2.1 DEFINITIONS AND CONCEPTS

2.1.1 Permafrost

Permafrost, or perennially frozen ground, is the thermal condition that exists when the ground (whether rock or unconsolidated material) remains at a temperature below 0°C for two or more years.

An important implication of this temperature-based definition is that it does not require the ground to be frozen. Thus, materials containing ice in the pore spaces and those that do not are both considered to be permafrost, provided the temperature condition (i.e. remaining at less than 0°C for two or more years) is met. Since the application of petrophysical logging techniques in this study is dependent on the recognition of physical changes in log response due to the presence of ice, it is convenient to follow Osterkamp and Payne (1981) in separating the two conditions. The former, therefore, is denoted as ice-bearing permafrost (IBPF) and the latter as permafrost per se (defined, as above, solely on the basis of temperature).

The base of permafrost corresponds to the position of the 0°C ground temperature isotherm at depth; as such, permafrost thickness may be delineated only on the basis of precise temperature surveys. The base of ice-bearing permafrost (IBPF), on the other hand, may be determined, as shown in this study, based on interpretation of petrophysical (downhole) well logs. These reflect the physical changes that occur in response to the phase change from pore water to ice.

The bases of permafrost and ice-bearing permafrost rarely, if ever, correspond, since there is generally a marked difference in temperature at the two depths. This temperature difference, termed the freezing point depression (FPD), is a function of pressure, chemical and soil particle effects (Osterkamp and Payne, 1981). D&S Petrophysical Consultants (1983) suggest FPD may range from about 1.28°C in coarse grained sands to as much as 8.24°C in shales. The impact of FPD may be illustrated by an example. Thus, assuming an average geothermal gradient for the Arctic Islands area of 30°C/km (tti Geotechnical Resources, 1983) and the above FPD values, the base of IBPF may be shown to vary from about 43 m above the 0°C isotherm in clean (i.e. non-shaly) sands to over 275 m above the isotherm in shales. An implication is that the lowest "ice" indications, picked from the electrical logs, in any well may actually be the lowest levels of gas hydrate occurrence. In this case, the base of permafrost could be at an appreciably higher level.

Most well logs also exhibit a transition zone below the IBPF base, within which the resistivity and sonic travel times gradually change. The results of this study indicate the thickness of the transition zone may range from about 10 m to

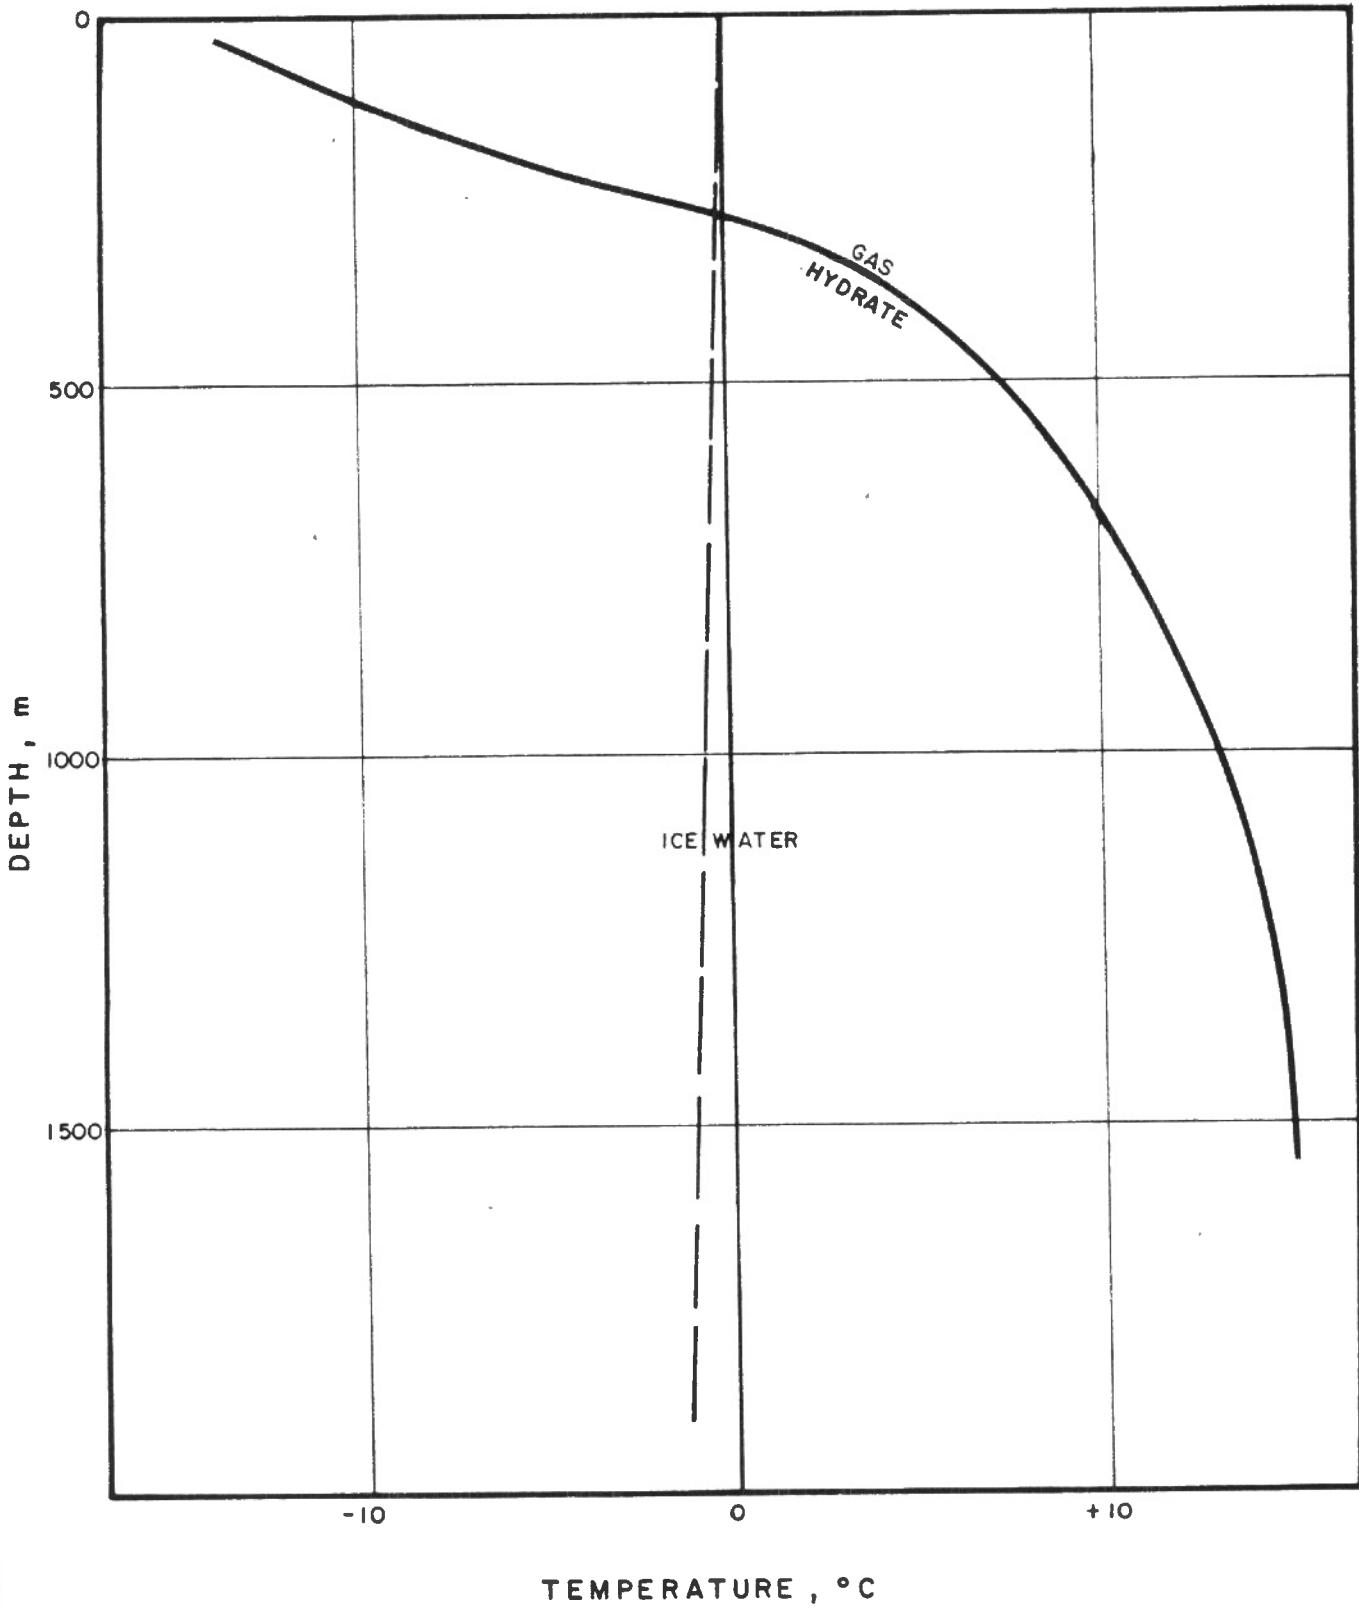

greater than 100 m. Likely, this is again a function, at least in part, of lithology (i.e. proportion of shale). Thermodynamically, however, ice and water will co-exist in fine pore spaces, so that the transition zone likely also represents the increasing unfrozen water content as the melting point is approached (Desai and Moore, 1968).

2.1.2 Natural Gas Hydrate

Natural gas hydrates, or clathrates, are solid, ice-like, mixtures of natural gas and water which, under pressure, can form at temperatures considerably above the freezing point of water.

The hydrate structure consists of a latticework of water molecules held together by hydrogen bonds, with the gas molecules filling in the voids. According to Davidson et al (1978), gas hydrates may be of two main types: Structure I formed by "small" gas molecules, such as methane and ethane, and Structure II containing larger molecules, such as propane and isobutane.

A phase diagram for the methane-water system, which is of primary importance in this study, is presented on Figure 2. As shown by Judge (1982) and others, superimposition of a measured (for example, E.P.B.) ground temperature profile on to the diagram, may provide an appreciation of whether or not the area is hydrate-prone. If so, the likely thickness of the hydrate-bearing interval may also be estimated.

2.2 PETROPHYSICAL LOG RESPONSE

Up to eight individual logs (run in varying combinations) are typically available for wells drilled within the study area. In most instances, the log exhibits a characteristic response as the logging tool moves up-hole, from unfrozen material into ice-bearing permafrost and through zones that may or may not contain natural gas hydrates.

The following sections categorize the petrophysical response (or lack thereof), based both on theoretical considerations and actual experience. Reference is made also to the results of earlier studies reported in the literature. Features that are of particular value in delineating IBPF and/or hydrate zones are highlighted.

2.2.1 Resistivity Logs (IES, EL, DLL, DILL, DISFL, Etc.)

In general, frozen porous formations are considerably more resistive than similar non-frozen materials. On this basis, an abrupt increase in resistivity can be expected at the base of IBPF. As noted by Hnatiuk and Randall (1977), however, this may not always be the case, since the resistivity increase may be masked by the effects of thermal invasion around the well bore. Fortunately, in most of the Arctic Island wells examined, an increase in resistivity can be observed. As a result, indications on the resistivity log (in combination with other features, such as drift in the spontaneous potential log) were used, in the majority of wells, as the primary indicator of the IBPF base.

Resistivity logs, generally of the Electrical Log (EL), Dual Lateralog (DLL), or Dual Induction Laterolog (DILL) types are available for almost all wells within the study area (see individual Analysis Details, Appendix "A").

2.2.2 Sonic (Acoustic) Logs (BHCS, S, LSS)

It is well documented, based on laboratory studies, that sonic (acoustic) velocities in porous formations are higher at low temperatures (i.e. when ice is present) than they are at higher temperatures. On this basis, a distinct shift from low to high velocity could be expected when passing up-hole into ice-bearing permafrost or through a hydrate zone (assuming a material of relatively uniform lithology and porosity). In practice, however, the opposite is usually the case, since thermal invasion and thawing cause the borehole walls to crumble and wash out, in both permafrost and hydrate-bearing zones. The result is "cycle skipping" that gives rise to spuriously slow travel times which completely obscure the real (faster) values.

As shown in Sections 2.4 and 2.5, "cycle skipping" may be put to use as a permafrost and (especially) hydrate indicator. It needs to be borne in mind at the same time, however, that other features (e.g. high porosity sands, presence of gas, fracturing) can also give rise to very slow acoustic travel times and cycle skipping. Thus, it is preferable to use a number of logs in combination rather than a single log to pick IBPF and/or hydrates.

Sonic logs are available for almost all Arctic Island wells. These are, in most instances, of the borehole-compensated type

(BHCS); however, long-spaced sonic (LSS) logs have also been run in some wells.

2.2.3 Spontaneous Potential Log (SP)

The SP curve records the difference in potential between a moveable electrode in the well and a fixed surface electrode (Hnatiuk and Randall, 1977). Characteristically, it shows a negative drift while moving uphole through permafrost, the start of which can often be used to locate the IBPF base or to confirm the pick determined from analysis of the resistivity logs. It is suggested the SP drift may be related to an increase in pore water salinity with depth (Desai and Moore, 1968; Pollard and Nash, 1971); however, according to Hnatiuk and Randall (1977), this is not proven.

Collett (1983) suggests that "there is a relatively lower (less negative) spontaneous potential deflection in a hydrate zone when compared to that associated with free gas".

SP logs are available, generally in combination with the resistivity log, for almost all wells considered.

2.2.4 Gamma Ray Log (GR)

This log, generally run in conjunction with sonic and caliper, measures the natural radiation of the formations surrounding the well bore. As might be expected, passing uphole into ice-bearing permafrost and/or through a hydrate zone has no direct influence on the GR log. However, the log was of value in this study for determining the distribution of sand (as opposed to shale) horizons and, thus, potential hydrate-

bearing zones. In the same way, non-correspondence of the GR with the SP was sometimes an indication of IBPF or hydrate intervals (see Section 2.6).

Gamma ray logs are available for almost all Arctic Island wells.

2.2.5 Caliper Log (C)

Drilling through permafrost and/or hydrates, using conventional mud, leads to the creation of a zone of thermal invasion. In all but the most competent formations, development of an overgauge hole often results, due to thawing, caving and hydrate decomposition. Such effects may range in severity from a mild rugosity of the borehole wall to a gross washout. They are readily identified on the caliper log.

Caliper surveys are usually run in combination with the sonic and density/neutron logs. As a result, they are available for almost all wells in the study area.

2.2.6 Formation Density Log (FD, FDEN)

There is a density difference between ice and water and also, probably, between gas hydrate and ice. Since the water, ice and/or hydrate components of any rock occupy only the pore spaces, the ability of the density log to distinguish between fluids or other substances within naturally occurring rock masses is significantly reduced. As a result, differences in density are likely too small to be recognizable directly.

Thawing of permafrost and decomposition of hydrates (due to an increase of temperature or decrease in pressure beyond critical levels) may, however, result in crumbling or even gross washout of the borehole walls. The density log is sensitive to hole irregularities (it becomes distorted to the point of being useless in a washed-out hole). Thus, it can indirectly indicate the presence of IBPF and/or hydrates. It may be noted, however, that in reacting in this manner, the density log is actually providing no more information than the caliper. Furthermore, it has also to be remembered that hole rugosity (and washouts) can be caused by a variety of factors other than thawing permafrost and/or decomposing gas hydrates.

Density logs are available for the majority of Arctic Island wells. They are run singly (FDEN) or with the compensated neutron (FD).

..2.7 Neutron Logs (CN, SNP), GRN

The neutron log responds to hydrogen ion concentration, small differences in which may exist between rock containing water, ice and gas hydrates. Such differences are very small, however, so that although theoretically possible (Collett, 1983), it is unlikely the neutron log can be used in practice to distinguish between permafrost, unfrozen materials and gas hydrate-bearing rock, directly.

Fortunately, like the density log, modern (pad-type) neutron tools are sensitive to hole washout. Thus, both "sidewall neutron" (especially) and the "compensated neutron" logs may indicate permafrost and gas hydrate occurrence indirectly, by reacting to hole rugosity or washout. The old (non pad-type)

neutron tools, on the other hand, are relatively insensitive to hole conditions and will contribute little or nothing to recognition of permafrost and hydrates.

All neutron logs are very sensitive to the presence of shale. As a result, even under perfect hole conditions, variations in the shale content of sands will likely mask any effects due to small variations in hydrogen ion content (associated with permafrost, unfrozen water bearing rock and gas hydrate bearing rock).

Neutron logs are available for most of the wells considered. Two types of log are predominant: "compensated neutron" (CN) and "sidewall neutron porosity" (SNP).

2.2.8 Temperature Log (TEMP)

Temperature surveys (run using a downhole tool, rather than a precise thermistor probe) are available for a number of wells. As described by Pollard and Nash (1971), the base of ice-bearing permafrost is generally indicated by a "plateau-like" feature; this is accompanied by a marked change in temperature gradient (Pollard and Nash, 1971: Figures 21, 22). The temperature log may be used to confirm the IBPF "picks" derived from other sources (e.g. resistivity logs).

2.3 OTHER DATA SOURCES

In addition to the petrophysical logs, mud gas logs, crystal cable data and detailed temperature surveys are also available for a limited number of wells. Characteristics of these data sources are described below.

2.3.1 Mud Gas Logs

This log provides a continuous record of drilling mud gas returns and, according to Collett (1983), "... serves as the best tool available for the differentiation of a hydrate saturated unit from gas-free ice-bearing permafrost". It is our experience that mud gas log peaks do indeed give confirmation of hydrate "picks" derived from other sources (e.g. sonic logs). However, some caution is necessary, since the logs may also exhibit relatively continuous gas shows related to water-bearing sands, that contain dissolved gas, or to continuing degradation of hydrates drilled through previously (i.e. higher in the well).

Mud gas logs for some 15 wells were reviewed (see side-by-side log presentations).

2.3.2 Crystal Cable Data

Crystal cable (downhole seismic velocity) surveys were reviewed for a limited number of wells. As noted by Hnatiuk and Randall (1977), "by recording seismic wave first arrival times to geophones suspended in the well from shot holes displaced horizontally from the well bore, a velocity plot which is not significantly influenced by the zone of thermal invasion can be plotted". Walker and Stuart (1976) have described the successful use of this technique in the Mackenzie Delta area.

In this study, crystal cable data were used to verify the petrophysical log picks only.

2.3.3 Detailed Temperature Surveys

Precise temperature surveys, which provide the only conclusive means of determining depths to the 0°C isotherm (and, thus, permafrost thickness), are available for some thirty Arctic Island wells. These data, collected by the Earth Physics Branch, EMR, form part of the Canadian Geothermal Data Collection - Northern Wells. Pertinent information is presented on Table 2; as described in Section 3.3.1, the E.P.B. data constitute a valuable control on the results of the present study. In all instances, E.P.B. depths to the 0°C isotherm have been converted to depths below kelly bushing (K.B.).

2.4 DETERMINATION OF PERMAFROST THICKNESS

The base of permafrost (IBPF) was picked on the logs of Arctic Island wells in four main steps, as follows:

- i) Firstly, E.P.B. data on depth to the base of permafrost (0°C isotherm) were reviewed for the well, if available, and, if not, for wells in the general area. The objective was to gain an appreciation of the likely frozen ground thickness to be anticipated.
- ii) The resistivity and spontaneous potential logs for the well were then examined. Moving uphole, an attempt was made to identify a relatively abrupt increase in resistivity that was associated with a negative drift in SP. Once this had been done (resistivity increase - SP drift was used to pick the base of IBPF in the great

majority of wells), the presence or absence of a transition zone below the IBPF base was determined.

- iii) After the likely bases of IBPF and the transition had been identified, based on resistivity and SP, the other logs were reviewed to provide confirmation. As described in Section 2.2, indications of IBPF include: hole washout, shown on the caliper (and often reflected in the neutron and density logs), non-correspondence between SP and gamma ray and cycle-skipping on the sonic. The selected IBPF and transition base depths were then confirmed or modified, as necessary.
- iv) Finally, a reliability factor was assigned to each pick, ranging from 1 (good) to 3 (relatively poor).

Interpreted IBPF and transition base depths are shown on the individual analysis detail sheets (Appendix "A") and the side-by-side log presentations (Appendix "C"). The results are summarized on Table 2, and described in Section 3.0.

2.5 IDENTIFICATION OF GAS HYDRATE OCCURENCE

Hydrates form where gas (methane in most Arctic Island wells) is present and their occurrence follows the same rules as apply for any other hydrocarbon accumulation: both a porous reservoir host rock and a trapping mechanism are required. Thus, hydrates occur preferentially in sand (or occasionally silt) units, and are found either throughout or at the top of the unit (since gas gravitates upward). In addition, more is needed than merely a high pressure and low temperature for hydrates to be present; even if pressure/temperature

TABLE 2

SUMMARY OF RESULTS

Well	EPB Data	IBPF	Likely Hydrate Occurrence				
Number	Name	0°C Isotherm (m)*	Base (m)	Trans. (m)	Overall Interval (m)	Thickness (m)	Comments
1	Garnier 0-21	497+	274	311	-	-	No hydrates logged.
2	Resolute Bay L-41	EX 600	518	-	942-1247	305	Probably hydrates throughout (to 1500 m +)
3	Devon E-45	X1 594	780	875	158-1600	1442	No hydrates logged.
4	Central Dome K-40	-	860	1021	-	-	No hydrates logged.
5	Young Bay F-62	-	253	277	-	-	No hydrates logged.
6	Russell E-82	-	305	349	158-387	229	Scattered hydrates only below 935 m.
7	Winter Harbour No. 1	E2 530	384	-	424-1862	1438	
8	Herne F-85	-	310	340	154-1510	1356	No hydrates logged.
9	Beverley Inlet G-13	-	308	357	-	-	No hydrates logged.
10	Allison R. N-12	-	396	454	969-1813	844	Traces of hydrate 969 - 1676 m.
11	Sabine Bay A-07	-	< 366	-	< 366-1714	> 1348	No IBPF within logged interval; crystal cable suggests IBPF base at 245 m.
12	Bathurst Caledonian R. J-34	-	808	846	433-1029	596	
13	King Point West B-53	-	296	335	-	-	No hydrates logged.
14	Apollo C-73	-	549	671	34-204	724	
15	Richardson Point G-12	-	747	768	27-751	724	
16	Weatherall 0-10	-	235	352	1126-1151	25	
17	Towson Point F-63	-	646	-	-	-	No hydrates logged.
18	Eldridge Bay E-79	-	509	631	300-768	468	
19	Ikkaliktok M-64	-	305	360	283-896	607	
20	Orksut I-44	-	616	680	354-931	577	
21	Nanuk D-76	-	< 603	-	675-1244	569	IBPF above DILL log top.
22	Kusruak D-16	-	434	503	-	-	No hydrates logged.
23	Victoria Is. F-36	-	235	290	-	-	"Saturated" DILL.
24	Tiritchik M-48	-	764	829	853-1250	937	
25	Storkerson Bay A-15	X 495	529	561	-	-	No hydrates logged.

conditions are favourable at a given location, hydrate may or may not be present, or extend to the limits of the theoretical hydrate envelope (Figure 2).

With these considerations and the previously-described diagnostic criteria in mind, gas hydrate occurrence was interpreted as follows:

- i) By reference to the methane stability curve and using measured temperature (E.P.B.) data from the closest instrumented well, the likely presence or absence of hydrates (at the well or in the general area) was determined. If the likely presence of hydrates was indicated, the approximate limits of the hydrate-prone zone was also noted. These data were used as a basis only for the interpretation; in practice, logs for all wells were reviewed, whether or not the presence of hydrates was anticipated.
- ii) The occurrence of likely hydrate-bearing intervals (i.e. sands) within the hydrate-prone zone was next determined, based on a review of the gamma ray log. Low GR readings opposite shales, due to grossly washed-out hole, were "screened out" by reference to the caliper log.
- iii) The likely presence of hydrates in the sands was then identified by reference to the other logs, as outlined in Section 2.2. Indications include: non-correspondence between SP and gamma ray, evidence of hole washout on the caliper and density or neutron (the density correction curve was often a good indicator), cycle

skipping on the sonic log, "tracking" of the GR and sonic and "hour-glassing" of the caliper and sonic.

- iv) Finally, the hydrate "picks" were compared with peaks on the mud gas logs, where available.

Results of the hydrate interpretation are shown on the individual analysis detail sheets (Appendix "A") and on the side-by-side presentations (Appendix "C"). In each instance, the estimated reliability of the pick is indicated, ranging from good (1, "hydrate") to fairly good (2, "? hydrate") to relatively poor (3, "possible hydrate"). The results are summarized on Table 2, with respect to limits of the hydrate prone zone and overall thickness.

2.6 SUMMARY

The diagnostic criteria developed in the preceding sections may be summarized, in point form, as follows.

2.6.1 Indications of the Base of Ice-Bearing Permafrost

In moving uphole, the following may be used in the Arctic Islands, generally in combination, as indicators of the base of IBPF:

- i) a relatively abrupt increase in resistivity
- ii) a negative drift of the S.P. log
- iii) hole washout, shown by the caliper log
- iv) non-correspondence between the S.P. and gamma ray logs
- v) cycle skipping on the sonic log, due to hole washout.

On most wells the presence of a transition zone, of variable thickness, below the IBPF base is also indicated.

2.6.2 Gas Hydrate Indications

When reviewing the petrophysical logs, the following were used to interpret occurrences of natural gas hydrate:

- i) a low gamma ray reading, indicating sand; plus
- ii) cycle skipping on the sonic log
- iii) non-correspondence between the S.P. and gamma ray logs
- iv) some degree of hole washout (on caliper)
- v) location in sand bodies (throughout or at top)
- vi) "tracking" of the GR and sonic logs and tendency for the caliper and sonic to "hour-glass"
- vii) peaks on the mud gas log, if available.

It should be emphasized that, in both permafrost and gas hydrate delineation, all available log (and other) information was reviewed before a preferred "pick" was selected. It may also be noted that the diagnostic criteria used in this study were developed for the Arctic Island wells. While they should be applicable, in theory, to permafrost/gas hydrate delineation in other areas, it has to be recognized that this may not necessarily be the case.

3.0 PERMAFROST THICKNESSES, ARCTIC ISLANDS

3.1 EXISTING INFORMATION

The Arctic Islands are entirely situated within the continuous permafrost zone so that frozen ground underlies almost all the land areas and, existing data suggests, many of the channels between islands (Judge 1974). Available site-specific information, on permafrost thickness is limited, however, and generally, from widely distributed sites.

Pre-1970's data have been summarized in a pioneer paper by Brown (1972). He concluded that permafrost might range in thickness from about 300 m in southern Victoria Island to 600 m in northern Ellesmere Island, and be considerably thicker in interior Ellesmere Island.

Since the early 1970's, more information has become available, primarily from abandoned hydrocarbon wells that have been instrumented by the Earth Physics Branch. Data from some 30 wells in the study area are now available (see Table 2). Measured permafrost thicknesses (i.e. depths, below K.B., to the 0°C isotherm) range from 138 m in Hecla I-69 to 718 m in Bent Horn N-72.

A number of permafrost depth estimates have also been published by industry, based on the application of petrophysical and geophysical techniques. Results of these studies (notably by Pollard and Nash (1971), Merritt (1979) and Acheson (1979)) are summarized, and compared with the findings of this investigation, in Section 3.3.

3.2 RESULTS OF THIS STUDY

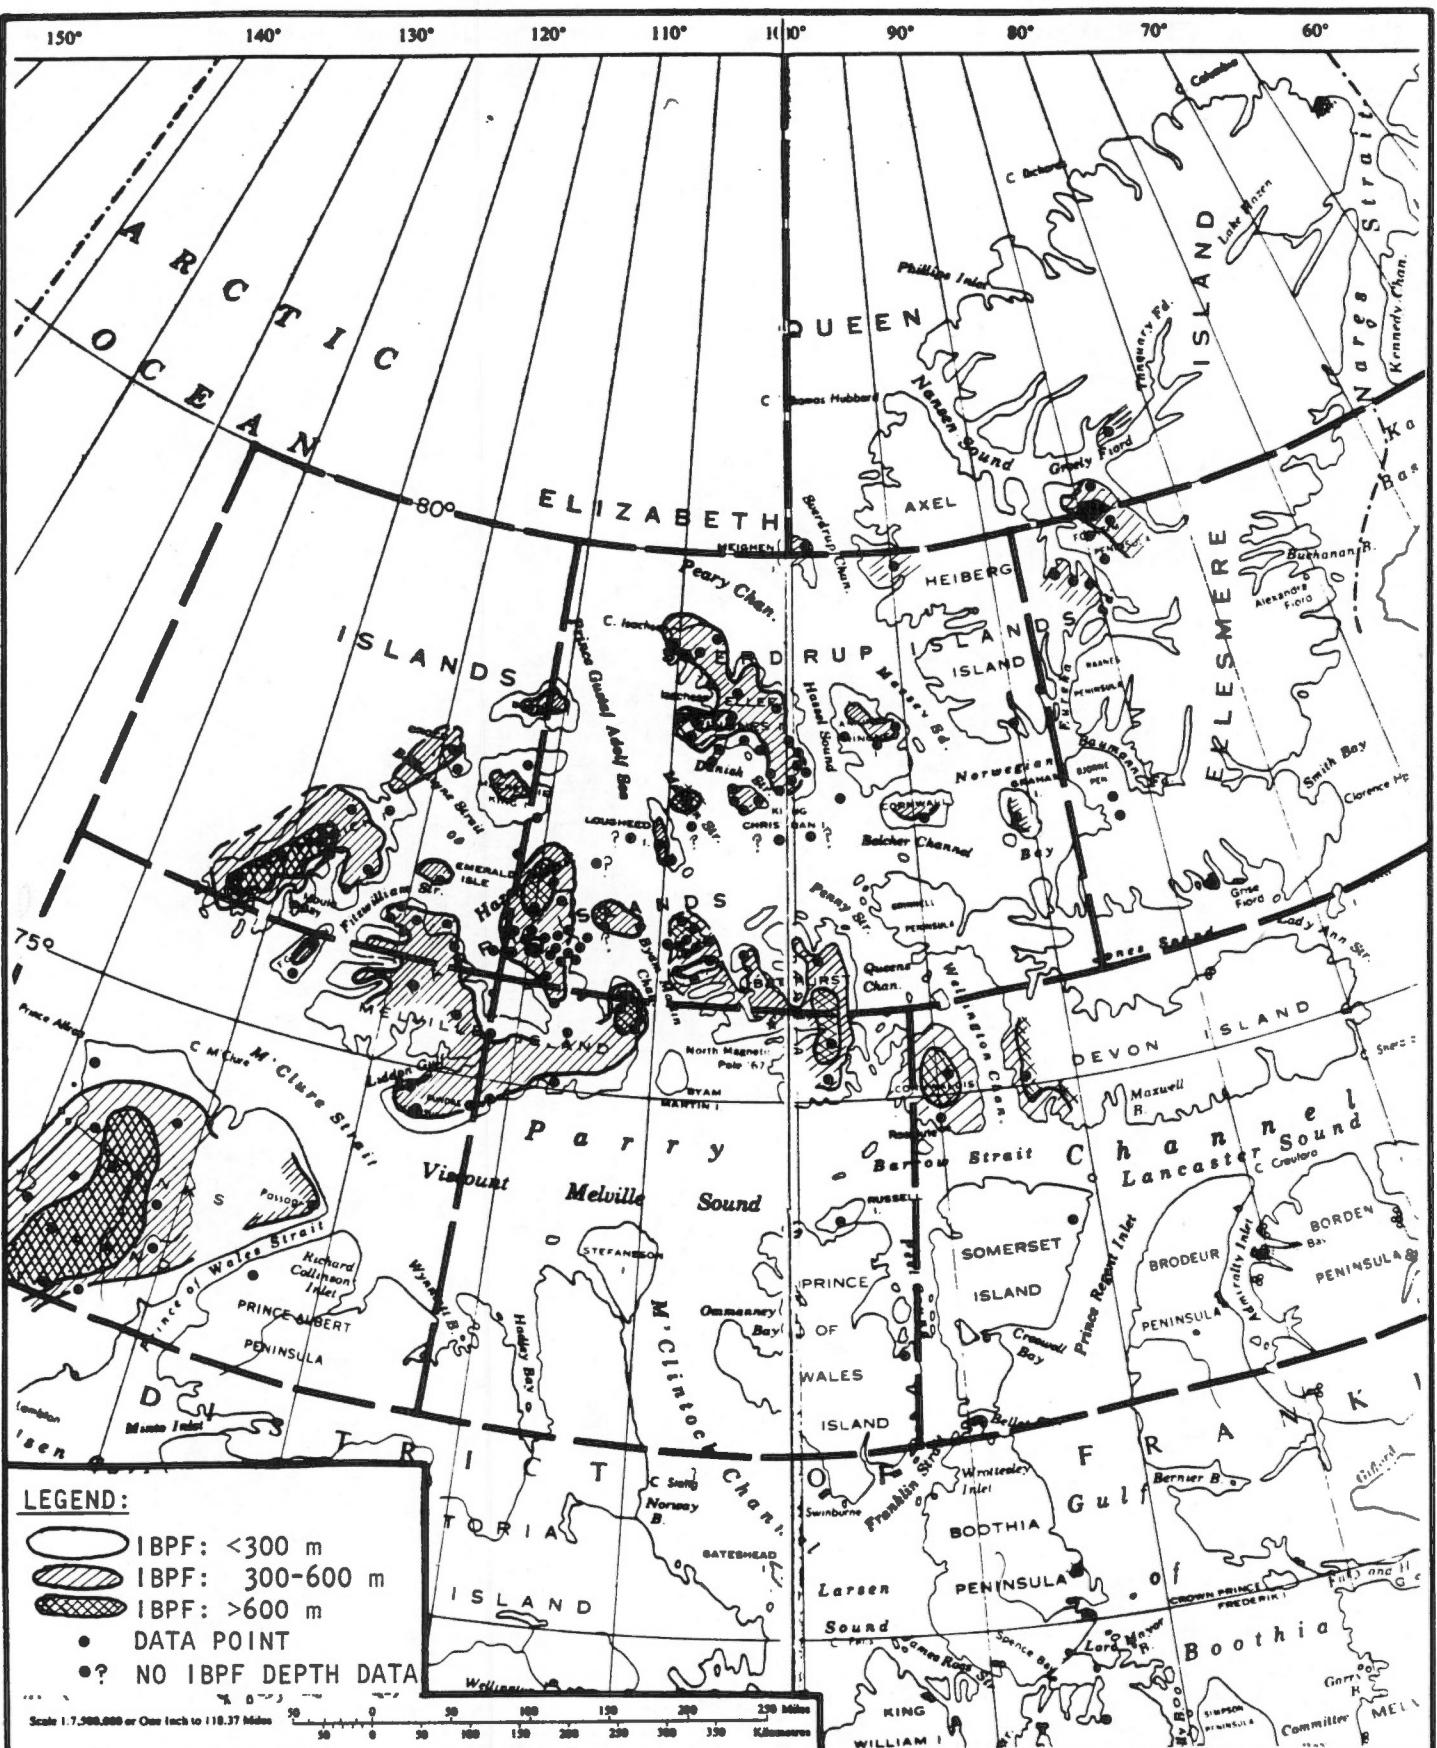

Interpreted depths to the base of IBPF in the study area are shown on Figure 3 and, in detail, on Maps 1 to 7 (Appendix "B", Volume 2). It should be noted that Figure 3 provides a generalized approximation only of IBPF depths and distribution, intended to provide an overall illustration of trends in the results of the study. The data, also presented with the related transition base depths on Table 2, are briefly discussed below.

3.2.1 Lancaster Sound (Map 1)

Interpreted IBPF depths range from 274 m on Somerset Island (Garnier) to 860 m in central Cornwallis Island (Table 2). The thickest permafrost interpreted during the study occurs at the latter site (Cornwallis Central Dome); deep permafrost also exists on Devon Island (Figure 3). Depths to the transition base at these sites vary from 311 m to 1021 m. A total of four wells are located within the Lancaster Sound map sheet; in each instance the reliability rating, assigned to the IBPF and transition base picks, was "relatively poor".

3.2.2 Viscount Melville Sound (Map 2)

Excepting sections of Melville and Bathurst Islands (where interpreted IBPF thicknesses exceed 600 m, ranging up to as much as 808 m), IBPF thicknesses are relatively consistent, in the 300 m to 500 m range (Figure 3). Less than 300 m of IBPF is interpreted in central Melville Island (Figure 3). Depths to the base of transition, at the 14 wells located in this map area, exhibit a similar trend: a minimum of 235 m in central

G10095

FIGURE 3

NTDB - 79/05

Melville Island and maximum of 846 m (Bathurst Caledonian R.) in central Bathurst Island (Table 2).

3.2.3 Thomsen River (Map 3)

Interpreted IBPF thicknesses exhibit considerable variation over relatively short distances, ranging from 764 m in eastern Banks Island (Tiritchik) to 235 m in northwestern Victoria Island (Map 3). Transition base depths range from 290 m to 829 m (Table 2). In all, 16 wells are located within the Thomsen River map area, primarily on Banks Island. The results suggest that thick IBPF (>600 m) is relatively widespread in central Banks Island (Figure 3).

3.2.4 Jones Sound (Map 4)

This map includes some nine relatively widely distributed wells, located on the Bjorne and Fosheim Peninsulas of Ellesmere Island and on Axel Heiberg Island. Interpreted IBPF thicknesses range from 252 m (Fosheim) to 716 m (Taleman), with corresponding transition base depths of 296 m to 762 m (Table 2).

3.2.5 Belcher Channel (Map 5)

A total of 91 wells are located within this map area. As in other sections of the study area, interpreted IBPF depths vary considerably, even over relatively short distances: from 131 m (Drake B-44, Linckens Island) to 779 m (Key Point West, on Vanier Island). A number of wells have also been drilled offshore. Interpreted IBPF base depths range up to 680 m (Skate) and 780 m (Roche Pt), however in most instances, the

IBPF base (if present) could not be picked (Table 2). Depths to the transition base in the Belcher Channel map area range from 224 m to 831 m.

As shown on Figure 3, thick permafrost (>600 m) is interpreted on Ellef Rignes, King Christian, and Cameron Islands, and in the northwestern Sabine Peninsula (including the offshore).

3.2.6 Ballantyne Strait (Map 6)

Permafrost (IBPF) thicknesses in the 14 wells in this map area are interpreted to range from 210 m (Satellite, in western Prince Patrick Island) to 701 m (on Emerald Island). Corresponding depths to the transition base are 271 m and 802 m, respectively. As shown on Figure 3, the study results suggest that thick permafrost is relatively extensive on Prince Patrick Island.

3.2.7 Robeson Channel (Map 7)

Only three, widely distributed, wells are located within this map sheet. Interpreted permafrost (IBPF) thicknesses range from 373 m to 494 m (Map 7), depths of the transition base from 495 m to 530 m (Table 2).

3.3 COMPARISON WITH PREVIOUS INTERPRETATIONS

In addition to the results of precise E.P.B. ground temperature surveys, a number of interpretations of permafrost thickness in Arctic Island wells have been published. Objectives in this section are to compare pertinent results of the present study with the previous interpretations.

3.3.1. Earth Physics Branch

Estimates of permafrost thickness, based on precise ground temperature surveys, have been published for a total of 30 Arctic Island wells. These results are contained in a series of publications concerning the Canadian Geothermal Data Collection - Northern Wells (Taylor and Judge, 1971, 1974, 1975, 1976; Judge et al, 1979, 1981; Taylor et al, 1982).

For comparison purposes, the E.P.B. permafrost depth estimates are presented with the corresponding interpreted IBPF and transition base depths on Table 2. A review of these data sets suggests the following:

- i) In most instances (24 wells out of 30), the correspondence between measured and interpreted results is good. Measured (0°C isotherm) permafrost depths at these sites are in excess of the IBPF and, often, transition base depths (the latter reflect the occurrence of ice bonding, rather than sub-zero temperatures per se). Depth differences range from 5 m or less, in the Jameson Bay C-31 and Dome Bay P-36 wells, to 170 m, at Neil 0-15 (Table 2). Such differences are apparently a reflection of freezing point depression effects, as described in Section 2.1.1.
- ii) At two sites (Hecla I-69 and Drake E-78), measured permafrost depths are considerably less than those interpreted.

iii) Available data for the Drake D-73, Drake Pt D-68, Wilkins E-60 and Louise Bay 0-25 wells are not adequate to provide a valid comparison (generally because an interpreted IBPF base depth is not available). The remaining results usually suggest a reasonable correspondence.

Based on the above, the comparison between E.P.B. measured permafrost thicknesses and those reported here is considered to be good.

3.3.2 Pollard and Nash (1971)

In this pioneer petrophysical study of permafrost conditions, Pollard and Nash make reference to ten Arctic Island wells. Table 3 provides a comparison with the results of this study.

Comparison is difficult in four instances since Pollard and Nash were unable to provide an interpretation of permafrost conditions. Of the six wells for which a direct comparison is possible, however, there is a reasonable to excellent correlation in four cases (Kitson R., Russell, Allison R. and Resolute Bay). In the Sandy Pt and Skybattle Bay wells, the correlation is relatively poor (Table 3).

3.3.3 Merritt (1979)

Based on seismic reflection data, Merritt interprets a distinct velocity break, at a depth of 610 m, as the base of ice bonded permafrost in the Robert Harbour K-07 well. Analysis of petrophysical logs as part of this study "picked"

TABLE 3

* Based on electric logs and temperature data.

** Based on near-surface seismic velocity data.

Analysis of petrophysical logs as part of this study "picked" the IBPF base at a depth of 622 m (Table 2). Agreement is, thus, very good.

3.3.4 Acheson (1979)

For ten wells in the Drake Point area, Acheson compares early estimates of permafrost thickness based on electric logs and temperature data, with more recent interpretations based on near surface seismic velocity data. The results are presented, together with pertinent data from this study, on Table 4.

Comparison with the Acheson results is not altogether favourable, since:

- i) in four wells (I-55, D-68, D-73 and K-33), the data are such that a comparison is not possible,
- ii) for the B-44 and F-14 wells, there is reasonable agreement,
- iii) interpreted permafrost thicknesses at the other sites are considerably greater than those published by Acheson.

3.3.5 Taylor and Judge (1981)

Taylor and Judge compare E.P.B. measured and predicted permafrost thicknesses for two closely spaced wells on Cameron Island: Bent Horn F-72A and Bent Horn N-72. Measured and predicted values (converted to metres below K.B.) were 653 m and 683 m, and 718 m and 738 m respectively (Taylor and Judge, 1981; Figure 4a).

HARDY ASSOCIATES (1978) LTD.
CONSULTING ENGINEERING & PROFESSIONAL SERVICES

INTERPRETED GAS HYDRATE OCCURRENCE ARCTIC ISLANDS

CG10095

FIGURE 4
HT08 - 79/95

Interpreted IBPF base depths of 587 m and 629 m for the F-72A and N-72 wells, and depths to the transition base of 701 m and 732 m, respectively, were obtained in this study (Table 2). These results suggest the closest comparison is between the E.P.B. predicted depths and the interpreted transition base (rather than IBPF) depths as would be expected.

3.4 SUMMARY

Depths to the IBPF base have been interpreted for 128 of the 151 Arctic Island wells considered. In three instances, the logs were run; in the others, the data do not permit a pick to be made.

The results of the study, shown in a generalized fashion on Figure 3, suggest that ice-bearing permafrost in excess of 600 m thick occurs on and generally in the interior of Banks, Devon, Cornwallis, Melville, Prince Patrick and King Christian Islands. Isolated occurrences of thick permafrost also apparently exist offshore. The shallowest interpreted IBPF depths are in the Sabine Peninsula and southern sections of the study area. In most other areas, interpreted IBPF thicknesses are in the 300 to 600 m range.

Comparisons with previous interpretations are variable. Agreement with temperature-based and petrophysical interpretations is generally fairly good. However, geophysical interpretations do not usually match very accurately.

4.0 GAS HYDRATE OCCURENCE, ARCTIC ISLANDS

4.1 EXISTING INFORMATION

Although Pollard and Nash suggested the likely presence of gas hydrates in the Arctic Islands in 1971, the first documented occurrences were reported from the Mackenzie Delta by Bily and Dick (1974). Subsequently, Hitchon (1974) and Hood (1980) recorded possible occurrences from the Arctic Islands (see Section 4.3).

Available information has recently been reviewed by Judge (1982). Based on comparison of observed temperatures and gradients relative to the methane stability curve, he proposed depths of occurrence and likely hydrate thickness ranging from 960 m and 820 m, respectively, in the eastern Arctic Islands. These increased to 1400 m and 1260 m, respectively, on the Arctic Platform (Judge, 1982: Table 1).

4.2 RESULTS OF THIS STUDY

Objectives in the sections that follow are to describe the interpreted distribution of natural gas hydrates. Maximum encountered depths and thicknesses within each of the previously-described map areas are summarized below. The basic data are presented on Table 2 and plotted on Maps 1 to 7. Figure 4 illustrates the overall distribution of interpreted hydrate occurrences and non-occurrences.

4.2.1 Lancaster Sound (Map 1)

Maximum interpreted depth of hydrate occurrence is 1600 m (in the Cornwallis Central Dome well), with an inferred hydrate interval thickness of 1442 m (Table 2). Hydrates are interpreted to be present in three of the four wells (Map 1).

4.2.2 Viscount Melville Sound (Map 2)

Ten of the fourteen wells in the Viscount Melville Sound map area are interpreted to have intersected hydrates. Maximum depths of occurrence range from 204 m to 1862 m (Winter Harbour No. 1); the theoretical hydrate-bearing zone at Winter Harbour may be in excess of 1400 m thick (Table 2).

4.2.3 Thomsen River (Map 3)

Natural gas hydrates are interpreted in nine of the sixteen wells. Hydrate zones ranging from 109 m to 1388 m in overall thickness are inferred. The maximum interpreted depth of occurrence of 1687 m in the Castel Bay well, in north-central Banks Island.

4.2.4 Jones Sound (Map 4)

Hydrate occurrence is apparently relatively widespread, with hydrates interpreted at 8 out of 9 sites. Maximum inferred depth of occurrence is 1836 m (Fosheim) and the thickest interpreted hydrate-bearing zone has a thickness of 1525 m (Table 2).

4.2.5

Belcher Channel (Map 5)

The relative complex distribution of hydrates in this map area is shown on Map 5. In general, hydrate occurrence is considerably less frequent than in other sections of the study area: in only 50 of 91 wells. With some exceptions (for example, in Bryam Martin Channel), hydrates are rarely interpreted in the offshore. On land, they are inferred infrequently in the Sabine Peninsula area.

Where present, hydrates are interpreted to occur to depths of as great as 1890 m (Bent Horn E-43). The thickness of the hydrate-bearing zone varies from 30 m to 1771 m (Table 2).

4.2.6

Ballantyne Strait (Map 6)

Nine of the fourteen wells located within this map area are interpreted to have intersected hydrates. As shown on Table 2, the maximum inferred depth of occurrence is 1952 m (Satellite), while the thickness of the hydrate-bearing zone ranges from 62 m to 1051 m.

4.2.7

Robeson Channel (Map 7)

Hydrates are apparently absent in the three wells located in this map area.

4.3

COMPARISON WITH PREVIOUS INTERPRETATIONS

Published reports of natural gas hydrate occurrence in the Canadian Arctic Islands are limited. The following sections

briefly describe the previous reports and interpretations and provide a comparison with the results of this study.

4.3.1 Hitchon (1974)

Reference is made by Hitchon (quoting A. Bryant, of Dome Petroleum) to a reported small gas flow, from the interval 319 m to 727 m, in the Winter Harbour No. 1 Well. As shown on the side-by-side log presentation for this well, the presence of gas hydrates is interpreted in three separate zones within the overall interval considered (453-538 m, 573-617 m, and 722-935 m). The reliability of the hydrate interpretation is rated fair to good.

4.3.2 Hood (1980)

In reporting the results of an oil industry survey, relative to experience with gas hydrates, Hood makes reference to one Arctic Islands well: Jackson G-16/G-16A. At this location, gas kicks and mud gas were encountered in the interval 522.9 to 600.3 m. Available information suggested a high pressure, low volume, free gas rather than hydrate source. The results of the present study are in agreement, since the occurrence of gas hydrates was not interpreted (see side-by-side log presentation in Appendix "C").

4.3.3 Judge (1982)

Judge presents predictions of possible gas hydrate occurrence for four Arctic Island wells, based on superimposing measured temperature profiles on the hydrate stability curve: Louise

0-25, Kristoffer Bay G-06, Bent Horn N-72, and ? Drake Pt B-44
(Judge, 1982; Figure 2).

According to Judge:

"Two of the superimposed temperature curves lie outside the methane-hydrate zone because, although mean surface temperatures are very low ..., geo-thermal gradients are high ... At these sites (Drake Point ... and Louise Bay ...), only free gas would be encountered within and below the permafrost. By contrast, the low geothermal gradients coupled with low subsurface temperatures at Kristoffer Bay ... and at Bent Horn ... indicate zones of possible gas-hydrate presence."

Results of the present study are in good agreement (Table 2). Thus, no hydrates were logged in the Louise and Drake Point wells (hydrates were, however, interpreted in other wells at Drake Point). Further, gas hydrates were logged in the intervals 154-619 m and 597-640 m, respectively, in the Kristoffer Bay and Bent Horn wells (Table 2).

4.4 SUMMARY

The overall distribution of areas of interpreted hydrate occurrence and non-occurrence is shown on Figure 4.

Hydrates are apparently widespread in the Arctic Islands, with thick hydrate-bearing zones extending to considerable depth. In general, hydrates are interpreted to be least abundant, and most sporadically distributed, in the Sverdrup Basin (e.g. Bent Horn and Drake Point areas). With some exceptions, hydrates are not widely interpreted in the offshore.

Comparison with previous interpretations is generally good.

5.0

DISCUSSION

This report presents the results of a study of permafrost conditions and gas hydrate occurrence in 151 Arctic Islands wells. Ice-bearing permafrost is interpreted to exist on land to depths ranging from 131 m (Linckens Island) to 860 m (Cornwallis Central Dome). It also occurs in the offshore; however, available data are inadequate to map its occurrence with any accuracy in the latter areas. Natural gas hydrates are interpreted in about 90 of the 151 wells, extending to depths ranging from 27 m to 1923 m.

A number of areas for potential future work have been identified, arising out of this study; most of these relate to additional petrophysical studies:

- i) Estimation of ice contents in IBPF, based primarily on analysis of resistivity and sonic logs,
- ii) Determination of hydrocarbon saturation in hydrates, based on petrophysical analysis,
- iii) Detailed analysis of mud gas logs, relative to various sources of gas, such as hydrates, dissolved gas in water sands, dry gas accumulations, gas associated with oil accumulations.

Mud Gas	-	-	-	-	-	-	-	-

C. DETAILED GAS HYDRATE INTERPRETATION

D. COMMENTS

Cycle skipping on BHCS due to lithology.
No hydrates logged.

ARCTIC ISLANDS PERMAFROST/GAS HYDRATES STUDY: ANALYSIS DETAIL

A. WELL INFORMATION

WELL NO.: 145
 D.A. No.: 504
 E.P.B. No.: -

K.B.: 25.3 m

NAME: Satellite P-68

T.D.: 3680.5 m

G.L.: 20.7 m

B. PERMAFROST AND GAS HYDRATE DATA

Log Name	Avail/Type	Logged Interval			Permafrost			Gas Hydrates
