La rectification
des périodes de couverture
de données annuelles et trimestrielles

- résumé -

Le document présente une méthode pour rectifier les périodes couvertes par des données annuelles et trimestrielles. Par exemple, des données annuelles couvrent les périodes d'avril à mars de l'année suivante; les valeurs rectifiées couvrent les périodes de janvier à décembre. Des variantes de la méthode conviennent aux séries de flux, de stock et d'indice. La méthode peut aussi s'utiliser pour désagréger des données annuelles (disons) en chiffres trimestriels ou mensuels.

- summary -

A method is presented to correct the reference periods of yearly and quarterly data. For instance, the available yearly data cover from April to March of the following year; the corrected values cover from January to December. Variants are proposed for flow, stock and index series. The method can also be used to disaggregate yearly data (say) into sub-annual figures.

INTRODUCTION

In many cases, statistical agencies receive annual data which pertain to the financial year (or "fiscal year") of the respondent. The reference period of that year may range from June 1 to May 31 for instance. However the statistician actually needs figures which pertain to the conventional year (or "calendar year") ranging from January 1 to December 31. The yearly data published by statistical agencies are indeed supposed to reflect the conventional year.

The problem is also aggravated by the fact that the reference period of the financial years may change from occasion to occasion for a given respondent: In 1982 (say), one company's report covers from April 1981 to November 1982; in 1983, from December 1982 to December 1983; in 1985 (no report in 1984), from January 1984 to June 1985; and so on.

The problem would be simple if the statistician had the sub-annual breakdown of the financial year values available. Unfortunately, this is generally not the case. Here is an example of how this may happen. In order to keep the response burden to questionnaires to a minimum,

statistical agencies ask a greater number of their respondents to fill detailed questionnaires on a yearly basis; and, a lesser number of respondents to fill summary questionnaires on a monthly or quarterly basis. One variable available yearly for a respondent may therefore not be available at all sub-annually or be available with a lower degree of reliability.

This paper provides a general method to convert financial year data into conventional year values. The problem is seen as a special application of interpolation between annual benchmarks, according to a variant of the modified Denton method (Denton, 1971; Cholette, 1984). The method consists of dis-aggregating the financial data into sub-annual values; and, of re-aggregating the sub-annual values into the desired conventional year values. When the dis-aggregated data are needed per se, they are then made available by the method proposed. In some applications, data of financial years ending in January (for instance) may be dis-aggregated into monthly data in order to be re-aggregated both in conventional year and in conventional quarter values

Variants of the method are derived for flow series, for stock series and for index series. An approach to correct the reference periods of quarterly data is outlined. The conversion of (bundles of) weekly data into monthly values is covered in another paper (Cholette, 1987a).

The paper unfolds according to Ehrenberg's (1982) recommendation about technical papers. Illustrations and results are presented first. Methodological details come later.

Flow series, irregular financial years

Figure 1: Estimated conventional year values when the financial years cover sometimes more and sometimes less than four consecutive quarters

Flow series, regular financial years

Figure 2: Estimated conventional year values when each financial year value cover four consecutive quarters

1. ILLUSTRATION OF THE METHOD FOR FLOW SERIES WITH IRREGULAR FINANCIAL YEARS

Flow series are such that they sum to the corresponding annual values, e.g. Retail Trade. The financial years of the flow series in Figure 1 have reference periods which vary from occasion to occasion. Their statistical usefulness is limited by the fact they are not comparable through time. The problem consists of converting those five available irregular financial years into six conventional values, each of which would cover 4 quarters.

Varying reference periods are not common in practice. Their use here is to illustrate the generality of the method. The available financial year data are actually represented in the figure by their averages over their reference periods, i.e. by their value divided by the number of periods covered. This allows their display on the same scale as the underlying quarterly series. The latter series is not available in practice. For the sake of illustration however, it is assumed known. The underlying series contains an obvious seasonal pattern, with a seasonal peak in the first quarter of each year and a trough in the third. The underlying trend-cycle component is not linear. It goes up from year 1 to year 3; down, for year 4 and 5; and then up again.

The figure finally contains the true conventional year values (computed from the underlying quarterly series) and the corresponding estimated values. Like the financial years, the true and the estimated conventional years are represented by their averages over their reference period. The estimated conventional year values were obtained by means of the conversion method proposed in this paper. Their percentage errors with respect to the true conventional year values are small: 0.1%, 1.0% -1.4% 0.8% -1.6% and 3.5% for years 1 to 6 respectively.

2. SIMPLE SOLUTION FOR FLOW SERIES WITH REGULAR FINANCIAL YEARS

Figure 2 describes a simpler and more common situation where all the available financial year values y^a_i (for year i) refer to 4 consecutive quarters. All values cover from the second quarter of one year to the first of the following year. In cases of such regular financial years, estimation may be greatly simplified under certain assumptions given later. Each estimated conventional year value y^d_i is a convex combination of the two closest financial year data:

$$(2.1) \quad y^d_i = (K y^a_{i-1} + (J-K) y^a_i) / J, \quad i=2, \dots, N-1,$$

or more specifically for the situation in Figure 2,

$$(2.1') \quad y^d_i = (1 y^a_{i-1} + 3 y^a_i) / 4, \quad i=2, \dots, 5.$$

In equation (2.1), J is the number of months per year (4 for quarterly and 12 for monthly series); and K is the number of "months" not in the conventional year reference period. A positive K means that K quarters wanted in year i are in fact in year $i+1$; and a negative K , in year $i-1$.

(For Figure 2, $K=1$ and $J=4$.) Variable N stands for the total number of conventional years referred to -however partially- by the financial years. (For instance a financial year covering from April 1981 to March 1982 refers to two conventional years, 1981 and 1982.)

financial years:	y^a_1	y^a_2	y^a_3	
	---+---	---+---	---+---	
quarters:	1 2 3 4	1 2 3 4	1 2 3 4	1 2 3 4
years:	1	2	3	4
	---+---	---+---	---+---	---+---
conventional years:	y^d_1	y^d_2	y^d_3	y^d_4

Figure 3: The reference periods of the central conventional years 2 and 3 are embedded in the reference periods of financial years 1 and 2, and of 2 and 3, respectively. The reference periods of conventional years 1 and 4 are not entirely embedded. In that sense, the corresponding conventional year estimates are forecasts, as opposed to interpolations.

The first and last desired values are respectively obtained by:

$$(2.2) \quad y^d_1 = ((J+K) y^a_1 - K y^a_2) / J,$$

$$(2.3) \quad y^d_N = (-(J-K) y^a_{N-2} + (2J-K) y^a_{N-1}) / J;$$

or more specifically in the situation of Figure 2,

$$(2.2') \quad y^d_1 = (5 y^a_1 - 1 y^a_2) / 4,$$

$$(2.3') \quad y^d_6 = (-3 y^a_4 + 7 y^a_5) / 4.$$

These end estimates are in a sense extrapolations or forecasts, because they involve extrapolated sub-annual values. This is illustrated in Figure 3. Their reliability is therefore lower than that of the central estimates of equation (2.1). Note that the end estimates do not have to be used in practice.

Figure 2 displays the conventional year values estimated by means of (2.1') to (2.3'). The percentage errors (with respect to the true desired conventional values) are -0.9%, 1.7%, -1.2%, -2.0%, 2.6% and 5.9% for years 1 to 6 respectively. The error is bigger for the last year (5.9%) because that estimate is in fact an extrapolation.

One attitude with respect to regular financial year values is to ignore the fact that their reference periods are wrong. In other words, the first available financial value is considered an estimate of the first conventional value; the second available value, of the second conventional value; etc. The resulting percentage errors are 2.1% for year 1, instead

of -0.9% with the proposed method; 4.4% for year 2, instead of 1.7%; 3.5%, instead of -1.2%; -3.8%, instead of -2.0%; and 3.7% for year 5, instead of 2.6%. (Doing this provides no estimate for year 6.) The errors are larger than with the method proposed and biased. The bias is positive in periods of increase in the (trend-cycle of) the underlying series; and negative in periods of decrease.

Equations (2.1) to (2.3) correspond to the solution for flow series and regular financial years, when the method proposed is applied on 3-year series intervals (two years of financial data). Appendix A provides the weights corresponding to a 5-year interval. Section 4 explains how the weights are derived.

3. ASSUMPTIONS ABOUT THE UNDERLYING SUB-ANNUAL SERIES

The variants of the financial year conversion methods described in this paper require some or all the following assumptions. Some situations make some of the assumptions unrealistic or even untenable. The statistician may then prefer to use a variant based on weaker assumptions. This section may actually be referred to evaluate the scope and the consequence of assumptions entertained.

The first assumption states that the series consists of the sum of four components: 1) the trend-cycle, 2) seasonality, 3) the irregular or random component and 4) the trading-day component:

$$(3.1) \quad z_t = c_t + s_t + I_t + D_t \quad \text{Assumption 1}$$

By definition, the seasonal component tends to cancel out over any 4 or 12 successive periods:

$$(3.2) \quad \sum_{j=1}^J s(i-1)J+j+K \rightarrow 0 \quad \text{Assumption 2}$$

where J is the number of months per year and i and j respectively stand for the year and the month considered.

The irregular or noise component has an expectation of zero. This implies it will tend to cancel out on K successive periods:

$$(3.3) \quad E(I_t) = 0 \rightarrow \sum_{k=1}^K I_{t+k} \rightarrow 0 \quad \text{Assumption 3}$$

The trading-day component is also centered on zero. It is therefore reasonable to assume that it tend to cancel out on any K successive periods:

$$(3.4) \quad \sum_{k=1}^K D_{t+k} \rightarrow 0 \quad \text{Assumption 4}$$

This last assumption is relevant only for monthly flow series. In that case, it is always verified if K equals 3. Indeed, (3.4) then constitute a quarter. Since all quarters have (almost) the same number of days, they

cannot display any trading-day variations.

The two first assumptions are common in all time series decomposition methods. (See Dagum, 1980; Shiskin et al., 1967; Harvey and Todd, 1983) Assumption 3 and 4 are valid if K is sufficiently large or if the component considered is small.

One more assumption may be needed. The trend-cycle is locally linear:

$$(3.5) \quad c_t = 2c_{t-1} - c_{t-2} + a_t, \quad a_t \rightarrow 0 \quad \text{Assumption 5}$$

This equation states that each value of the trend-cycle basically lies on the straight line running through its previous two values. This variant of linearity is that chosen by Boot, Feibes and Lisman (1967) for the interpolation of time series; by Leser (1961, 1963) and Schlicht (1981) for specifying the trend-cycle component in time series decomposition methods. Linearity can be justified by the fact that many socio-economic series display a long-term trend. This trend is always well approximated by local linearity. Deviations from linearity mostly take the form of acceleration or deceleration.

The available financial years y^a_i and the desired conventional year y^d_i may be respectively written as:

$$(3.6) \quad y^a_i = z_{(i-1)J+1+K_i} + z_{(i-1)J+2+K_i} + \dots + z_{iJ+K_i} \\ \text{(read } K_i \text{ instead of } K_i)$$

$$(3.7) \quad y^d_i = z_{(i-1)J+1} + z_{(i-1)J+2} + \dots + z_{iJ}$$

For $i=5$, $K_i=3$, $J=12$ (3.6) and (3.7) are respectively:

$$(3.6') \quad y^a_5 = z_{52} + z_{53} + \dots + z_{60} + z_{61} + z_{62} + z_{63}$$

$$(3.7') \quad y^d_5 = z_{49} + z_{50} + z_{51} + z_{52} + \dots + z_{59} + z_{60}$$

For K_i constant and positive ($K_i=K>0$), i.e. for regular financial years containing J "months" and under Assumption 1, the difference between the desired and available yearly values is

$$(3.8) \quad y^d_i - y^a_i = \sum_{k=1}^K (c_{(i-1)J+k} - c_{iJ-k+K+1}) + \sum_{j=1}^J s_{(i-1)J+j} - \sum_{j=1}^J s_{(i-1)J+j+K} \\ + \sum_{k=1}^K (I_{(i-1)J+k} - I_{iJ-k+K+1}) + \sum_{k=1}^K D_{(i-1)J+k} - \sum_{k=1}^K D_{iJ-k+K+1}$$

For $i=5$, $K=3$ and $J=12$ that difference reads:

$$y^d_5 - y^a_5 = [c_{49} - c_{61} + c_{50} - c_{62} + c_{51} - c_{63}] \\ + [(s_{49} + s_{50} + \dots + s_{60}) - (s_{52} + s_{53} + \dots + s_{63})]$$

$$(3.8') \\ + [(I_{49} + I_{50} + I_{51}) - (I_{61} + I_{62} + I_{63})] \\ + [(D_{49} + D_{50} + D_{51}) - (D_{61} + D_{62} + D_{63})]$$

Under Assumption 2, the second term in brackets (of eq. (3.8) or (3.8')) cancels out. Assumption 3 cancels the third term if I_t is small or K is large. Assumption 4 cancels the fourth term, if D_t is small or K is large or equal to 3.

When it is possible to make Assumptions 1 to 4, the difference between the conventional and the financial years is solely determined by the first term, that is by the year-to-year differences in the trend-cycle c . If Assumption 5 is also true, i.e. c is linear, regular financial years also behave linearly. Furthermore, the line in the latter -which is observable- is the same as that in the trend-cycle. The difference between the conventional and the financial can then be known exactly. More generally, the conversion is exact to the extent the trend-cycle (linear or not) of the underlying sub-annual series can be measured from the annual data. The conversion is guaranteed to be exact under linearity. This is the principle of the conversion method proposed, and this is why it works even if the trend-cycle is not linear.

4 SPECIFICATION FOR FLOW SERIES WITH REGULAR FINANCIAL YEARS

This Section considers flow series, when all financial years refer to four consecutive quarters, that is when K is constant. This is the more simple situation depicted in Figure 2. The conversion from financial to conventional years may then be simplified, if the five assumptions of Section 3 are made. Assumption 2 implies neither the available financial year data nor the desired conventional year estimates contain seasonality. The problem reduces to dis-aggregating the financial year into non-seasonal values ($c + I + D$) and to re-aggregating the sub-annual values into conventional years. The underlying series may contain seasonality. Its estimates are not required however, because they would cancel out in the re-aggregation process.

For similar reasons Assumptions 3 and 4 can further reduce the problem, namely to dis-aggregating the financial data into sub-annual trend-cycle values. The difference between the conventional and the financial year is known through (3.8), provided that the trend-cycle is linear, i.e. provided Assumption 5 is made. Linearity is maximized by minimizing the following objective function:

$$(4.1) \quad f(c) = \sum_{t=3}^{IJ} (c_t - 2c_{t-1} + c_{t-2})^2$$

where I is the number of conventional years in the series interval considered ($I \leq N$). The extent to which linearity is possible is governed by constraints:

$$(4.2) \quad \sum_{j=1}^J (c_{(i-1)J+j+K}) = y^a_i, \quad i=1, \dots, I-1.$$

These state that the values sought have to sum to the available financial year values.

The solution to that constrained minimization problem is developed in Appendix B (for more general variants of the method). The desired trend-cycle values are weighted averages of the available financial values:

$$(4.3) \quad c_t = \sum_{j=1}^J w_{t,m}^K y^a_m \quad t=1, \dots, IJ$$

The desired conventional year values are then simply the annual sums of the sub-annual trend-cycles values:

$$(4.4) \quad y^d_i = \sum_{m=1}^{(I-1)} c_{(i-1)J+j}, \quad i=1, \dots, I.$$

If the trend-cycle estimates are of no interest in themselves, the desired conventional values can be expressed directly in terms of the available ones (by substituting (4.3) in (4.4)):

$$(4.5) \quad y^d_i = \sum_{m=1}^{(I-1)} p_{i,m} y^a_m, \quad i=1, \dots, I$$

The weights $p_{i,m}$ depend only on I , the number of years in the series interval; on J , the number of months per year; and on K , the number of months not in the conventional year. They do not depend on the observations y^a_i . They can therefore be applied to any series interval -or any series- with the same values of J and K . In other words, they can be calculated once and for all.

This is why Appendix A provides tables of weights for $I=5$, $J=4$ and 12 and for relevant values of K . We would recommend their implementation in a 5-year moving average manner:

$$(4.6) \quad \begin{array}{lll} y^d_1 = \sum p_{1,m} y^a_m & \text{end year} & (\text{extrapolation}) \\ y^d_2 = \sum p_{2,m} y^a_m & \text{non-central year} & (\text{interpolation}) \\ y^d_n = \sum p_{3,m} y^a_{n-3+m}, \quad n=3, \dots, N-2, & \text{central years} & (\text{interpolation}) \\ y^d_{N-1} = \sum p_{4,m} y^a_{N-5+m} & \text{non-central year} & (\text{interpolation}) \\ y^d_N = \sum p_{5,m} y^a_{N-5+m} & \text{non-central year} & (\text{extrapolation}) \end{array}$$

where all summations take place over m going from 1 to 4. For $I=3$, the weights and their implementation are given by equations (2.1), (2.2) and

(2.3).

5. SPECIFICATION FOR FLOW SERIES WITH IRREGULAR FINANCIAL YEARS

This Section considers flow series, when one does not want to make all the assumptions made in Section 4 or when the reference periods of the financial year data are irregular. The latter case is the more complex case depicted in Figure 1. Financial year values covering sometimes more and sometimes less than 12 months (4 quarters) contain the seasonal values of the months in excess or missing in the reference period. Consider for instance a year referring to 15 periods, from March to May of the following year. The 12 months which appear once are likely to cancel out in the financial year, by virtue of Assumption 2. However, the seasonal values of the extra March, April and May are part of the financial year considered. (Seasonality cancels out over 12 months but not necessarily over three.) In that sense, such financial year data do contain seasonality. And this fact must be taken into account in dis-aggregating into sub-annual values. In other words, the dis-aggregated sub-annual values must reflect seasonality.

As for the irregular and the trading-day components, Assumptions 3 and 4 may still be reasonable. (This statement will deserve qualification later on.) In other words, these components still tend to cancel out. The sub-annual values needed must therefore only comprise the trend-cycle (like before) and the seasonal components $\zeta_t = c_t + s_t$. An appropriate objective function is:

$$(5.1) \quad f(\zeta) = \sum_{t=3}^{IJ} (\zeta_t/x_t - 2\zeta_{t-1}/x_{t-1} + \zeta_{t-2}/x_{t-2})^2$$

where x_t is an approximative seasonal pattern chosen by the subject matter expert of the series. For simplicity the values of x_t may be the same for each same month over the whole series interval considered. A value equal to 1.5 means that the month is 50% higher than an average month; equal to 0.6, 40% lower. A value of 1.0 specifies the month to be average; and a value of 0.0001, practically null. Only the relative values of x_t matter.

The meaning of objective function (5.1) is then the following. The desired sub-annual trend-cycle-seasonal values ζ should be proportional to the seasonal pattern x ; and the proportion ζ/x should change as linearly as possible. (Strictly speaking, Assumption 1 is being approximated by $z = \zeta + I + D$, where $\zeta = c + s$. The new objective function is minimized subject to the following constraints:

$$(5.2) \quad \sum_{t=\tau_m}^{\rho_m} \zeta_t = y_m^a, \quad \rho_m \geq \tau_m, \quad m=1, \dots, M.$$

These constraints state that the desired sub-annual values ζ_t must sum to the available financial data, whatever the reference periods $[\tau_m, \dots, \rho_m]$.

The solution is developed in Appendix B. As in the case of regular financial years, the desired sub-annual trend-cycle-seasonal values ζ_t are weighted averages of the available financial year values:

$$(5.3) \quad \zeta_t = \sum_{m=1}^M w_{t,m} y_m^a \quad t=1, \dots, IJ$$

They may be used as such or aggregated into conventional quarterly or into conventional year values (or both). The conventional year values for instance are simply the annual sums of the sub-annual trend-cycles values:

$$(5.4) \quad y_i^d = \sum_{j=1}^J \zeta_{(i-1)J+j}, \quad i=1, \dots, I.$$

The desired conventional values may be expressed directly in terms of the available ones (by substituting (5.3) in (5.4)):

$$(5.5) \quad y_i^d = \sum_{m=1}^M p_{i,m} y_m^a, \quad i=1, \dots, I$$

The weights do not depend on the financial year values. They do depend however on the distribution of their references periods, on the seasonal pattern chosen and on J and I. This implies they have to be calculated for each new series interval. According to Appendix A, this involves multiplications and inversion of matrices with dimension IJ by IJ. Such calculations may be prohibitive, especially if they have to be conducted at each respondents level for instance. They can be immensely reduced by means of a numerical approximation proposed in Cholette (1987a).

In many cases Assumption 4 may not be realistic. Indeed an important trading-day component will not cancel especially if K is small (and different from 3). Objective function (5.1) is still relevant if x is defined as the product of the seasonal and trading-day pattern ($x = s D$). The trading-day value D for a month is the sum of all the daily rates of activity d in the month, divided by the number days in the month t. The denominator should be 30.4375 if s is equal to 1, i.e. in the absence of seasonality (for more details see Cholette, 1987a.) Similarly to the seasonal pattern, those daily rates are more easily expressed with respect to the average of the week.

The estimated conventional year values of Figure 1 were estimated with the variant presented in this Section, with I=5, J=4 and with a appropriate seasonal pattern x.

Correcting quarterly data

Figure 4: Quarters corrected by the method proposed for a stock series

6. GENERALIZATION TO STOCK AND TO INDEX SERIES

The two variants of the method presented until now only addressed flow series. This section indicates the changes required to accommodate stock and index series. Objective function (4.1) is special case of (5.1), where x_t equals 1 and ζ_t equals c_t . Further developments will therefore start from the latter. The objective function is then:

$$(6.1) \quad f(\zeta) = \sum_{t=3}^{IJ} (\zeta_t/x_t - 2\zeta_{t-1}/x_{t-1} + \zeta_{t-2}/x_{t-2})^2$$

The unknown ζ_t may represent the trend-cycle in case of regular financial years, i.e. for K constant; or, the aggregate of the trend-cycle and the seasonal components for K not constant. Variable x may be equal to 1.0 for K constant; and must be equal to an expert-supplied seasonal pattern for K not constant.

6.1 Stock series

The annual values of stock series (considered here) correspond to one of the sub-annual values. Unless the underlying sub-annual series is non-seasonal, it can no longer be assumed that the financial year and the conventional years do not contain seasonality. Indeed their values will always depend on the quarter or month chosen. A seasonal pattern x_t (different from 1.0) is then required in objective function (6.1).

The appropriate constraints for stocks series are particular cases of (5.2):

$$(6.2) \quad \zeta_{tm} = y_m^a, \quad m=1, \dots, M \quad (\text{read } t_m \text{ instead of } tm)$$

According to Appendix B, the conventional year estimates are weighted averages of the financial values like in equation (5.5). These have to be recalculated for each series (interval).

6.2 Index series

The annual values of index series correspond to the average of the sub-annual values. (Flow and stock series expressed as indexes, e.g. the Index of Industrial production in the first case, the Consumer Price Index and Unemployment in the second case, are considered as index series for the purpose of the method.) The appropriate constraints are:

$$(6.3) \quad \sum_{t=\tau_m}^{\rho_m} \zeta_t / (\rho_m - \tau_m + 1) = y_m^a, \quad \rho_m \geq \tau_m, \quad m=1, \dots, M,$$

or more conveniently,

$$(6.3') \quad \sum_{t=\tau_m}^{\rho_m} \zeta_t = (\rho_m - \tau_m + 1) y_m^a, \quad \rho_m > \tau_m, \quad m=1, \dots, M.$$

The latter equation is a particular case of (5.2) if y_m^a is appropriately redefined.

When the reference periods of the financial year are irregular, x_t is seasonal index and solution (5.5) applies. For index series, however, financial years should be regular. In that case, assumption 2 is valid, so that x_t may be set to 1.0 and ζ_t to c_t (unless Assumption 4 cannot be justified). The solution is then the same as (4.5) except y^a_t is redefined, and the weights have the same convenient properties.

7. CORRECTING THE REFERENCE PERIODS OF QUARTERLY DATA

The problem discussed for yearly data is also encountered for quarterly data. For instance, the reference period of available quarterly data may cover December to February, March to May, etc., instead of January to March, April to June, etc. The reference periods may also be irregular.

A variant of the conversion method proposed can correct the reference periods of available quarterly data. These are dis-aggregated into monthly values which are then re-aggregated into the desired conventional quarters. An appropriate objective function is still a particular case of (5.1)

$$(7.1) \quad f(\zeta) = \sum_{t=3}^{3I} (\zeta_t/x_t - 2\zeta_{t-1}/x_{t-1} + \zeta_{t-2}/x_{t-2})^2$$

where I now stands for the number of quarters ($I \geq 5$) in the series interval considered. The objective function specifies that the desired monthly values should remain proportional to some expert-supplied monthly seasonal-trading-day pattern x . Objective function (7.1) is minimized subject to constraints (5.2), where y now represent the available quarterly data. The solution is derived in Appendix B in matrix algebra, or the numerical solution proposed by Cholette (1987a) may be used. As in the other variants of conversion, the corrected quarterly estimates are a linear combination of the available quarters. Those weights depend on x and I . Figure 4 illustrates an example of quarterly stock data corrected for reference periods. The available quarterly values refer to the February, May, August, November, February, etc., instead of March, June, September, December, March, etc. The estimation error of the corrected quarters (with respect to the true quarters) read -0.2%, -0.1%, 0.0%, 0.0%, 0.0%, 0.2%, -0.1%, -0.1% and 0.4% for the nine quarters. When considering the available quarters as estimates of the desired ones, the errors are much bigger 12.0%, -6.1%, -9.1%, 2.9%, 16.0%, -2.6%, -9.4%, 0.8% and 8.3%.

8. DISCUSSION

The approach proposed for correcting the reference periods of yearly (and quarterly) data is based on assumptions about the underlying monthly series and in many cases on user-supplied seasonal or seasonal-trading-day patterns. Sometimes, an underlying monthly series does exist, but is inconsistent with the yearly data. The coverage of respondents may be different; the reliability, lower; etc. When such a monthly indicator is available, the conversion problem should be solved in the context of benchmarking, in our opinion. This recommendation is especially relevant

when the corrected data are generated to be used as benchmarks for the corresponding sub-annual series.

Carrying out the conversion in the context of benchmarking would work as follows.

1) For one socio-economic variable, respondents with the same financial years are aggregated. Obviously, the level of aggregation must be lower than that of publication. If a seasonal index x_t is used, the aggregation must involve respondents with presumably common seasonal (and trading-day) pattern (for the variable considered).

2) The same aggregation is carried out "annually" and sub-annually. Annual discrepancies are then observed between the annual and the sub-annual data.

3) The sub-annual data is benchmarked to the "annual" data. In the benchmarking process, the annual data are specified to pertain to the reference periods which they actually cover (and not to the conventional years). The result at this point is a sub-annual benchmarked series consistent with the available yearly data.

4) The conventional year values are then calculated as the annual sums (or relevant operation) of the benchmarked series.

An appropriate objective function for proportional benchmarking (subject to (5.2)) is the following:

$$(8.1) \quad \sum_{t=2}^T (z_t/x_t - z_{t-1}/x_{t-1})^2$$

Variable x_t is the available sub-annual information. The unknown z_t is the desired sub-annual benchmarked series consistent with the financial year data. This function specifies that the ratio of the benchmarked series to the original is as constant as possible. This specification imputes the sub-annual missing respondents (in $z - x$) proportionally to the ones available (in x). In other words, the missing respondents behave like the available ones. That behaviour is also governed by the observed annual discrepancies.

An objective function for additive benchmarking:

$$(8.2) \quad \sum_{t=2}^T ((z_t - x_t) - (z_{t-1} - x_{t-1}))^2$$

This function assumes that the behaviour of the missing respondents (i.e. of $z - x$) is governed exclusively by the movement of the annual discrepancies. The behaviour would be constant if the annual discrepancies were constant; linear; sine-like; etc.

Objective function (8.1) and (8.2) use first differences instead of second differences previously. Indeed in the context of benchmarking the indicator x_t is presumably also an indicator of the trend-cycle. This was not in the previous sections. The indication of the trend-cycle was then achieved by second differences. We would actually advocate the use of first differences in the previous sections if the indicator chosen also indicated the trend-cycle. *The case*

The advantages of correcting the reference periods in the context of benchmarking are the following.

1) The conversion is no longer based on assumptions but on facts about the sub-annual series. Those facts are explicitly and operationally incorporated in the conversion process. (Note that benchmarking does not assume that the movement of the original sub-annual series is reliable, but that it is better than nothing; see Cholette, 1987a.)

2) When the variables involved in the conversion have to be benchmarked, both the conversion and benchmarking are achieved in a single operation.

When a respondent has a unique reporting pattern and/or provides no sub-annual values: The sub-annual values of other respondents may be used as sub-annual indicator.

The correction of the reference periods of quarterly data in the context of benchmarking is handled in a way similar to that of annual data.

The benchmarking approach to conversion proposed in this section is in a sense already used in some surveys conducted by Statistics Canada. The Shipments, Inventories and Orders surveys for instance collect sub-annual and annual stocks series. The reference periods of the financial year values are corrected on the basis of the movement in the available sub-annual data. If for instance the variable considered rose by 5% sub-annually from December to March, then the financial year value pertaining to March is reduced by 5% to make it refer to December. That procedure implicitly assumes that objective function (8.1) has reached its minimum of zero; in other words, that a sub-annual series consistent with the financial year values would have the same growth rates as the sub-annual series actually available. (Two series exactly proportional to each other have identical growth rates.) The benchmarking strategy proposed here is a refinement of that procedure: It uses the exact growth rates required for consistency.

More information about benchmarking may be found in Denton (1971), Cholette, (1984, 1987) and Laniel (1986).

One practice with respect to financial year data is the following (Bustros, 1986). The data of respondents with any of the twelve possible financial years ending between April (say) of year i and March of year $i+1$ are assigned to year i ; and for the variable considered, the annual value y is ruled to be the sum of all the data in any of the twelve financial years assigned to year i . Such a scheme causes biases in the trend-cycle movement of the resulting annual values. The nature of the biases also

depends on the phase of the business cycle and even on the variable considered (Cholette, 1987c). The under-estimation of the 1981-82 recession by the Canadian annual Retail Trade data, which are derived in that manner, confirms that contention.

CONCLUSION

It is technically possible to convert financial year data, with reference period ranging from April to March for instance, into conventional year data, with reference period ranging from January to December. Under the method proposed the desired conventional year estimates are weighted moving averages of the available financial year data.

In all variants of the method, assumptions about the underlying sub-annual series have to be made (see Section 3). Namely the trend-cycle component is linear and the seasonality is constant.

For flow and index series, these assumptions are sufficient to derive acceptable conventional year estimates, provided the reference periods of the financial years are regular and cover no more than 12 months (e.g. always June to May). The computations involved are also tremendously simplified: the weights of the moving averages are known in advance (see Appendix A) and do not require calculation for each new application.

For stock series or when the reference periods of the financial years are irregular (e.g. one year January to March, the next year April to March, April to December, etc.), the assumptions about the underlying series are not sufficient to derive acceptable estimates. The user has to supply a seasonal pattern and possibly a trading-day pattern for the underlying sub-annual series. The computations involved are also much more time-consuming: The weights of the moving averages are not known in advance and have to be recalculated for each application.

The same approach can also be used to correct the reference period of quarterly data. Both assumptions and user-supplied monthly seasonal and/or trading-day pattern are required.

In cases where some sub-annual data is available, we recommend solving the conversion problem within the framework of benchmarking. The conversion no longer rely on assumptions about the underlying series and on user-supplied seasonal-trading patterns, but on facts. As explained in Section 8, the desired conventional year values are then the annual sums (or relevant operation) of the sub-annual benchmarked series.

ACKNOWLEDGEMENT

I am most thankful to my colleague Jocelyn Plourde for his valuable assistance.

APPENDIX A: Five-year weights for converting financial year flow data when the financial years all cover 4 quarters or 12 months.

The row numbers in the tables indicate which conventional year i in the 5-year interval is estimated by the weights in the row. The column number m indicates to which available financial year the weight $p_{i,m}$ applies. For instance for $J=4$ and $K=1$

$$y^d_2 = 0.15152y^a_1 + 0.97760 y^a_2 - 0.15976 y^a_3 + 0.03064 y^a_4$$

Parameter K stands for the number of months or quarters which should be in conventional year i , but are actually in year $m+1$ for positive K or in year $i-1$ for negative K . The weights are the same for $K=-1$ and $K=J-1$; for $K=-2$ and $K=J-2$; and so on. The weights are therefore given only for positive values of K .

Furthermore, the weights are the same for $K=1$ and $K=J-1$, for $K=2$ and $K=J-2$, except the rows and the columns are in the reverse order. This can be verified for the quarterly weights for $K=0$ and 4 and $K=1$ and 3. In order to save space, the weights will not be given in the monthly case for K greater than 6.

Quarterly weights $p_{i,m}$:

APPENDIX B: Derivation of the solution of the general variant of the conversion problem

The problem is specified on a series interval containing I years and J "months" per year. The solution is first developed for correcting the reference periods of financial years; and then, of quarterly data.

Conversion of Yearly Series

Objective function (6.1) may be rewritten in matrix algebra as

$$(B.1) \quad f(Z) = Z'X^{-1}A X^{-1}Z$$

where

$$(B.2) \quad Z' = [\zeta_1 \zeta_2 \dots \zeta_{IJ}]$$

$$(B.3) \quad X^{-1} = \begin{bmatrix} 1/x_1 & 0 & 0 & \dots & 0 \\ 0 & 1/x_2 & 0 & \dots & 0 \\ \cdot & \cdot & \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot & \cdot & \cdot \\ 0 & 0 & \cdot & \cdot & 1/x_{IJ} \end{bmatrix}$$

$$(B.4) \quad A = D_2'D_2, \quad D_2 = \begin{bmatrix} 1 & -2 & 1 & 0 & \dots & 0 & 0 & 0 \\ 0 & 1 & -2 & 1 & \dots & 0 & 0 & 0 \\ \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot \\ 0 & 0 & 0 & 0 & \dots & 1 & -2 & 1 \end{bmatrix}$$

IJ×IJ (IJ-2)×IJ

The unknowns ζ_t represent the sub-annual trend-cycle values for flow and index series, provided all financial years are regular, i.e. all refer to J consecutive "months". The unknowns are the product of the trend-cycle and of the seasonal components, and of the trading-day component if applicable, in ALL other cases: stock series, and flow or index series with irregular financial years.

Symbols x_t represent known values. They are equal to 1 in case of flow and index series, provided all financial years are regular. They are equal to an expert-supplied seasonal pattern, multiplied by a trading-day pattern if applicable, in ALL other cases. Matrix D_2 is the second difference operator; and matrix A , the corresponding quadratic second difference operator.

Constraints (5.2) are written as:

$$(B.5) \quad H^a Z = Y^a,$$

where

$$(B.6) \quad H^a = \begin{matrix} & \text{columns:} & \tau_1 & & \rho_1 & & \tau_2 & & \rho_2 \\ \begin{matrix} M \times IJ \\ \\ \\ \end{matrix} & \begin{matrix} \\ \\ \\ \end{matrix} & \begin{bmatrix} 0 & 0 & \dots & 0 & 1 & 1 & \dots & 1 & 0 & \dots & 0 & 0 & \dots & 0 & 0 & 0 & \dots \\ 0 & 0 & \dots & 0 & 0 & 0 & \dots & 0 & 0 & \dots & 1 & 1 & \dots & 1 & 0 & 0 & \dots \\ \cdot & \cdot & & \cdot & \cdot & & \cdot & \cdot & & \cdot & \cdot & & \cdot & \cdot & & \cdot \\ \cdot & \cdot & & \cdot & \cdot & & \cdot & \cdot & & \cdot & \cdot & & \cdot & \cdot & & \cdot \\ \cdot & \cdot & & \cdot & \cdot & & \cdot & \cdot & & \cdot & \cdot & & \cdot & \cdot & & \cdot \end{bmatrix} \end{matrix}$$

$$(B.7) \quad Y^a = [y^a_1 y^a_2 \dots y^a_M]$$

Matrix H^a is a sum operator. With τ_m equal to ρ_m and appropriate values, the matrix can also act a month selector matrix for stock series.

Vector Y^a contains the available financial year values. These values have been multiplied by J in case of index series.

For simplicity, the constraints are introduced as a quadratic term in an augmented objective function:

$$(B.8) \quad F(Z) = Z'X^{-1}AX^{-1}Z + g (H^a Z - Y^a)'(H^a Z - Y^a)$$

where g is sufficiently large (e.g. 1000) to cause the term to reach the minimum (zero), that is to make the term equivalent to constraints in practise.

Performing the matrix operations in (B.8) yields:

$$(B.9) \quad F(Z) = Z'X^{-1}AX^{-1}Z + g Z'H^a H^a Z - 2g Z'H^a Y^a + g Y^a Y^a$$

In order for (B.9) to reach its minimum with respect to ζ_t , the derivatives of the objective function with respect to ζ_t must by definition equal zero:

$$(B.10) \quad \begin{aligned} dF/d\zeta &= 2 X^{-1}AX^{-1} Z + 2g H^a H^a Z + 2g H^a Y^a - 0 \\ &\rightarrow [X^{-1}AX^{-1} + gH^a H^a] Z - g H^a Y^a \end{aligned}$$

This implies the estimated sub-annual values are linear combinations, i.e. weighted averages of the available financial values:

1010319598

- 24 -

$$(B.11) \quad \rightarrow Z = [X^{-1}AX^{-1} + gH^aH^a']^{-1} g H^a y^a = W^s y^a$$

IJ x M

The estimated conventional year values are then the annual sum (or the appropriate operation) of the estimates sub-annual values:

$$(B.12) \quad y^d = H^d' Z = H^d' W^s y^a = p y^a$$

I x M

where H^d' is the I IJ annual sum operator (similar H^a) for flow and index series; and the appropriate observation selection matrix in case of stock series.

Correction of Quaterly Data

For correcting quarterly data, y^a now contains the available quarterly values, J is equal to 3, and I represents the number of quarters in the series interval. The augmented objective function is still (B.8)

Doing the same developments as for the yearly conversion, yields a similar result. The estimated sub-annual values are linear combinations, i.e. weighted averages of the available financial values:

$$(B.13) \quad Z = [A + gH^aH^a']^{-1} g H^a y^a = W^s y^a$$

I 3 M

The estimated quarterly values are then the quarterly sums (or the appropriate operation) of the estimates sub-annual values:

$$(B.14) \quad y^d = H^d' Z = H^d' W^s y^a = \overset{P}{W^y} y^a$$

I M

Matrix H^d' is the I by 3I quarterly sum operator for flow and index series

$$(B.15) \quad H^d = \begin{bmatrix} 1 & 1 & 1 & 0 & 0 & 0 & \dots & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 1 & 1 & \dots & 0 & 0 & 0 \\ \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \ddots & \vdots & \vdots & \vdots \\ 0 & 0 & 0 & 0 & \dots & 1 & 1 & 1 \end{bmatrix};$$

I x I 3

and the appropriate monthly selector for stock series.
