**TECHNICAL REPORT SERIES
CANADIAN WILDLIFE SERVICE**

This series of reports, established in 1986, contains technical and scientific information from projects of the Canadian Wildlife Service. The reports are intended to make available material that either is of interest to a limited audience or is too extensive to be accommodated in scientific journals or in existing CWS series.

Demand for these Technical Reports is usually confined to specialists in the fields concerned. Consequently, they are produced regionally and in small quantities; they can be obtained only from the address given on the back of the title page. However, they are numbered nationally. The recommended citation appears on the title page.

Technical Reports are available in CWS libraries and are listed in the catalogue of the National Library of Canada in scientific libraries across Canada. They are printed in the official language chosen by the author to meet the language preference of the likely audience, with a résumé in the second official language. **To determine whether there is significant demand for making the reports available in the second official language, CWS invites users to specify their official language preference. Requests for Technical Reports in the second official language should be sent to the address on the back of the title page.**

**SÉRIE DE RAPPORTS TECHNIQUES DU SERVICE CANADIEN
DE LA FAUNE**

Cette série de rapports donnant des informations scientifiques et techniques sur les projets du Service canadien de la faune (SCF) a démarré en 1986. L'objet de ces rapports est de promouvoir la diffusion d'études s'adressant à un public restreint ou trop volumineuses pour paraître dans une revue scientifique ou l'une des séries du SCF.

Ordinairement, seuls les spécialistes des sujets traités demandent ces rapports techniques. Ces documents ne sont donc produits qu'à l'échelon régional et en quantités limitées; ils ne peuvent être obtenus qu'à l'adresse figurant au dos de la page titre. Cependant, leur numérotage est effectué à l'échelle nationale. La citation recommandée apparaît à la page titre.

Ces rapports se trouvent dans les bibliothèques du SCF et figurent aussi dans la liste de la Bibliothèque nationale du Canada utilisée dans les principales bibliothèques scientifiques du Canada. Ils sont publiés dans la langue officielle choisie par l'auteur en fonction du public visé, avec un résumé dans la deuxième langue officielle. **En vue de déterminer si la demande est suffisamment importante pour produire ces rapports dans la deuxième langue officielle, le SCF invite les usagers à lui indiquer leur langue officielle préférée. Il faut envoyer les demandes de rapports techniques dans la deuxième langue officielle à l'adresse indiquée au verso de la page titre.**

Sex and age–specific distributions of sea ducks wintering in the Strait of Georgia, British Columbia: Implications for the use of age ratios as an index of recruitment

ABSTRACT

Management of sea duck populations in North America has been hampered by a lack of effective population monitoring tools. In this study, we used sex and age ratios calculated from direct visual counts to assess the demographic structure of the nine most common sea duck species wintering in the Strait of Georgia, British Columbia: Black Scoters (*Melanitta nigra*), Surf Scoters (*M. perspicillata*), White-winged Scoters (*M. fusca*), Harlequin Ducks (*Histrionicus histrionicus*), Barrow's Goldeneye (*Bucephala islandica*), Common Goldeneye (*B. clangula*), Bufflehead (*B. albeola*), Common Mergansers (*Mergus merganser*), and Red-breasted Mergansers (*M. serrator*). Shore-based surveys were conducted along 49 1-km transects during February 2003 and 62 transects in 2004. Our objectives were to estimate species' sex and age-specific abundance, evaluate distribution patterns, and determine whether multiple species surveys are suitable for monitoring annual variation in sea duck recruitment rates.

Results indicated that adult sex ratios were male-biased, with a particularly strong skew evident among Black and Surf Scoters (3.5 and 2.3 males per female, respectively). With respect to male age ratios, the proportion first year male was low for the five species for which they could be estimated (M_{1Y}/M_{TOTAL}: 0.14 ± 0.03 SE for Black Scoters; 0.07 ± 0.02 SE for Surf Scoters; 0.08 ± 0.02 SE for Harlequin Ducks; 0.07 ± 0.01 SE for Barrow's Goldeneye; 0.12 ± 0.02 SE for Common Goldeneye). This result was not surprising, given that sea duck life-histories are characterized by female-only parental care, high adult survival, and low annual productivity. However, for some species the age ratios we documented would not be sufficient to compensate for adult mortality, raising the possibility that detection biases or segregated distribution patterns preclude reliable population-level age ratio estimation. We cannot reject the possibility that unknown numbers of first year males are misidentified due to the difficulty of visually distinguishing individuals in exceptionally adult male or female-like plumages, and that male age ratios underestimate recruitment. Some segregation of the sex and age classes among habitat types was apparent within the Strait of Georgia, but the magnitude of distributional biases was generally quite small. Potential distributional biases at larger spatial scales should be investigated.

We conclude that winter sex and age ratio surveys are a reliable, inexpensive means of gathering important demographic data. However, several important considerations must be made before incorporating such data in population models. These include: quantifying the degree to which age ratios might be underestimated; determining the validity of using male age

i

ratios to infer female age ratios and ensuring that estimates are drawn representatively from the population as a whole; and determining the spatial scale at which wintering aggregations must be studied to ensure valid inferences about population processes.

RÉSUMÉ

La gestion des populations des canards de mer en Amérique du Nord souffre d'un manque d'outils de surveillance efficaces. Dans cette étude, nous avons utilisé les rapports des sexes et les rapports immatures-adultes calculés à partir des décomptes visuels directs pour évaluer la structure démographique des neuf espèces les plus communes de canards de mer qui hivernent dans le détroit de Georgia, en Colombie-Britannique : macreuses noires (*Melanitta nigra*), macreuses à front blanc (*M. perspicillata*), macreuses brunes (*M. fusca*), arlequins plongeurs (*Histrionicus histrionicus*), garrots d'Islande (*Bucephala islandica*), garrots à oeil d'or (*B. clangula*), petits garrots (*B. albeola*), grands harles (*Mergus merganser*) et harles huppés (*M. serrator*). Des relevés à terre ont été effectués en suivant 49 transects de 1 km en février 2003 et 62 transects en 2004. Notre objectif était d'estimer l'abondance des spécimens selon leur âge et leur sexe, pour chaque espèce, d'évaluer leur distribution et de déterminer si des relevés multiples permettent de suivre correctement les variations annuelles du taux de recrutement chez les canards de mer.

Les résultats indiquent que le rapport des sexes était en faveur des mâles, avec un déséquilibre marqué dans le cas des macreuses noires et des macreuses à front blanc (3,5 et 2,3 mâles par femelle, respectivement).Pour ce qui est du rapport immatures-adultes des mâles (M_{1an}/M_{TOTAL}), il était faible pour les jeunes mâles d'un an des cinq espèces : 0,14 ± 0,03 pour les macreuses noires; 0,07 ± 0,02 pour les macreuses à front blanc; 0,08 ± 0,02 pour les arlequins plongeurs; 0,07 ± 0,01 pour les garrots d'Islande; 0,12 ± 0,02 pour les garrots à œil d'or). Ces résultats ne sont pas surprenants puisque seules les femelles prennent soin des petits chez les canards de mer, que le taux de survie des adultes est élevé et que la productivité annuelle est faible. Toutefois, pour certaines espèces, le rapport des sexes que nous avons mentionné, s'il était réel, ne serait pas suffisant pour que la mortalité des adultes soit compensée et il est donc possible qu'il existe des erreurs systématiques dans les observations ou que des anomalies de distribution empêchent l'estimation fiable du rapport des sexes au niveau des populations en question. Nous ne pouvons pas rejeter la possibilité qu'un nombre inconnu de mâle d'un an soient mal identifiés, compte tenu de la difficulté de distinguer à vue les mâles des femelles à cet âge, et que le rapport immatures-adultes pour les mâles sous-estime le recrutement. Les différents types d'habitat dans le détroit de Georgia semblent avoir une légère influence sur l'effectif des classes de sexe et d'âge mais cet effet reste généralement assez faible. Il serait nécessaire d'étudier l'éventuel existence d'effets plus marqués de l'environnement sur les distributions à des échelles spatiales plus grandes.

Nous concluons que les relevés d'hiver visant à calculer les rapports des sexes et les rapports immatures-adultes constituent une méthode fiable et économique de recueillir des données démographiques importantes. Il faut cependant faire plusieurs mentions importantes avant d'incorporer ces données dans les modèles démographiques. Notamment : quantifier le degré maximal de sous-estimation des rapports des sexes; déterminer la validité d'utiliser les rapports immatures-adultes pour les mâles pour déduire les rapports équivalents pour les femelles et s'assurer que ces évaluations sont extraites de manière représentative en utilisant l'ensemble de la population; déterminer l'échelle spatiale à laquelle les rassemblements hivernaux doivent être étudiés pour bien comprendre les processus démographiques.

LIST OF FIGURES

1   INTRODUCTION

Recent evidence has indicated that sea duck (Anatidae: Mergini) populations are declining in North America (Sea Duck Joint Venture 2001, Goudie *et al.* 1994). The reasons for these declines are unknown and detailed ecological data are needed to ascertain both the mechanisms underlying population changes and the life stages at which they are occurring. Monitoring efforts that incorporate demographic data can lend important insight into population processes; however, management of North American sea duck species has been hampered by a lack of effective population monitoring tools.

Recruitment, the process by which young birds are added to the breeding population, is a crucial component of avian demographics. In waterfowl populations, recruitment is typically inferred using techniques such as pair-brood ratios (e.g. Kirby 1980, Rumble and Flake 1982), nesting success rates (e.g. Milne and Reed 1974; Klett *et al.* 1988, Traylor *et al.* 2004), and age ratios based on wings turned in by hunters (e.g. Bellrose *et al.* 1961). However, these techniques have been of limited value for sea duck species for several reasons. First, the core ranges of many sea ducks falls outside the areas traditionally covered in breeding bird surveys. Additionally, sea ducks tend to nest in lower densities and initiate breeding later in the season than the dabbling and diving duck species for which our current monitoring regimes were designed. Finally, in the Pacific Flyway, sea ducks rarely appear in hunter bags (Bartonek 1994), which results in sparse data for evaluating trends in population age structure and recruitment using programs like the Migratory Bird Harvest Wing Bee.

One alternative for indexing recruitment by sea ducks is the use of age ratios calculated from direct visual counts on non-breeding areas. This technique relies upon differences in plumage appearance between adults and young to distinguish cohorts and evaluate the demographic structure of populations. Unique sub-adult plumages have been described for males of several North American sea duck species (Palmer 1976, Bellrose 1980), and recent studies have used these differences to calculate sex and age ratios on specific wintering grounds (Duncan and Marquiss 1993, Rosenberg and Petrula 1998, Smith *et al.* 2001, Mittelhauser *et al.* 2002, Rodway *et al.* 2003, Iverson *et al.* 2004). Preliminary efforts are underway to incorporate these data into population models (Robertson *in press*), and the approach appears to have considerable potential as a management tool.

The objective of this study was to expand upon previous research and use mid-winter survey data to assess the sex and age structure of sea duck populations in the Strait of Georgia, British Columbia. We focused on the nine most common species: Black Scoters (*Melanitta*

nigra), Surf Scoters (*M. perspicillata*), White-winged Scoters (*M. fusca*), Harlequin Ducks (*Histrionicus histrionicus*), Barrow's Goldeneye (*Bucephala islandica*), Common Goldeneye (*B. clangula*), Bufflehead (*B. albeola*), Common Mergansers (*Mergus merganser*), and Red-breasted Mergansers (*M. serrator*). We used shore-based counts to derive sex and (when possible) age ratio estimates. Specifically, our objectives were to (1) quantify species densities, (2) determine sex and age ratios, (3) evaluate potential patterns of sex or age-related habitat segregation that might bias estimates, and (4) make recommendations as to as the utility of multiple species winter sex and age ratio surveys as an evaluation and monitoring tool.

2 METHODS

2.1 Study area

The sheltered marine waters of the Strait of Georgia (49.5°N, 123.5°W) are home to regionally and globally significant populations of waterbird species, including sea ducks (Butler and Vermeer 1989, Campbell *et al.* 1990). The area also has experienced burgeoning human population growth during the past 100 years, creating numerous challenges for wildlife populations. Habitats available to sea ducks in the Strait of Georgia range from rich estuaries around Baynes Sound and the Fraser River Delta to rocky fjord-like shorelines along the Sunshine Coast. Some areas, such as Burrard Inlet have highly industrialized foreshores, while others, such as the Discovery Islands at the northern end of the Strait, remain largely undeveloped. The survey locations described in this report encompass the full range of habitats available to sea ducks in the Strait.

2.2 Survey timing and coverage

Mid-winter surveys were conducted during February 2003 and 2004. The surveys were timed for mid-winter because that is the period of time when age-related plumage differences are most distinct (Smith *et al.* 1998, Iverson *et al.* 2003) and distributions of wintering birds are most stable (Rodway *et al.* 2003, D. Esler and S. Boyd *unpublished data*). During 2003, counts were made at 49 sampling locations, each encompassing a 1-km shoreline transect. Based on preliminary analyses, 13 additional 1-km survey transects were added in 2004 to increase statistical power. The survey transects were grouped into eight different geographic regions within the Strait of Georgia: (1) Boundary Bay/Fraser Delta, (2) Burrard Inlet/English Bay, (3) Southern Sunshine Coast, (4) Northern Sunshine Coast, (5) Discovery Islands, (6) Campbell River/Comox, (7) Baynes Sound/Hornby Island and (8) Deep Bay/French Creek. The selection of survey transects was based on prior experience by the research team, with emphasis placed

on sites known to contain a high density of at least one target species. Appendix 1 provides the latitude and longitude of start and end points for each transect, as well as driving directions and physical descriptions of each site.

2.3   Survey protocol

All survey counts were conducted from shore by experienced observers using a spotting scope and binoculars. Data were collected only during daylight hours (08:00-16:30), when Beaufort scale sea conditions rated as 3 (small scattered whitecaps, gentle breeze, wind speed 12-19 knots) or less. Observers walked the length of each 1-km transect counting all sea ducks within 500 m of shore. Sex (M = male; F = female) and male age class (ADU = adult, ≥ 12 months old; 1Y = first-year, < 12 months old) class was recorded for five species for which previous research has indicated such determinations were possible: Black Scoters, Surf Scoters, Harlequin Ducks, Barrow's Goldeneye, and Common Goldeneye. For the remaining four target species—White-winged Scoters, Bufflehead, Red-breasted Merganser, and Common Merganser—first year males are difficult to distinguish from females without having specimens in hand, therefore individuals were categorized only as adult male (M_{ADU}) or other (F_{ADU}, F_{1Y}, M_{1Y}). Identification of the plumage characteristics that distinguish sex and age cohorts requires training. Manuscripts by Smith *et al.* (1998) and Iverson *et al.* (2003), which detail the plumage differences for Harlequin Ducks and Surf Scoters, respectively, should be consulted by those interested in implementing similar surveys. Photographic records of Black Scoters, Surf Scoters, Barrow's Goldeneye, and Common Goldeneye also were used, which may be obtained by contacting the authors.

In large flocks (>50 individuals) sex and age determinations often could not be made for every individual due to birds being underwater or obstructed from view by other birds. For these flocks a preliminary scan was made to estimate the total abundance of each species, followed by a secondary scan to determine age and sex composition on a species by species basis. The secondary scan proceeded slowly over flocks and was timed to occur when a minimum of birds were in motion or diving.

2.4   Data analysis and interpretation

2.4.1   Sample sizes and linear densities

For each species, the number of birds encountered was totalled according to shoreline transect. Appendix 2 contains the raw data tabulated in this format. Each block was approximately 1-km in length, which allowed conversion of abundance estimates into linear densities (birds km^{-1}). Annual comparisons were made using linear densities because the

number of transects surveyed was increased during the second year of the study. The maximum number of individuals observed per transect and the percentage of transects that were occupied by at least one bird also were estimated. Mean densities are presented ± 1 SE.

   2.4.2   Sex and age ratios

   The ratio of adult males to total birds (M_{ADU}:Total) was estimated for all nine target species. For Black Scoters, Surf Scoters, Harlequin Ducks, Barrow's Goldeneye, and Common Goldeneye male age ratios (M_{1Y} :M_{TOTAL}) and population sex ratios (M_{TOTAL}:F_{TOTAL}) also were calculated. Because recruitment among waterfowl is commonly indexed as the ratio of fledgling females to adult females (Cowardin and Blohm 1992) F_{1Y} to F_{ADU} ratios also were calculated. In order to do so, we assumed a 1:1 ratio between first-year males and first-year females [F_{1Y}:F_{ADU} = M_{1Y}:(F_{TOTAL} - M_{1Y})]. It should be noted that the age of first breeding for sea ducks is thought to be ≥ 2 years of age; hence this estimate of female age ratio is an underestimate of the actual ratio of 1Y to adult breeding females. Mean sex and age ratios are presented ± 1 SE.

   Annual variation in sex and age ratios was assessed using generalized linear model ANOVA. Separate analyses were performed for each species. The models employed a binomial error distribution, treating sex and age class as binary response variables, and used a logit link function to bound parameter estimates between 0-1. The Wald test statistic (*W*) was used to judge statistical significance at the α = 0.05 level. For Surf Scoters, three additional years of data published by Iverson *et al.* (2004), were included in the analysis in order to examine longer-term patterns in sex and age ratio variation (2000-2004). The historical data for Surf Scoters were collected using point counts at 36-57 sample locations in the Strait of Georgia from 2000-2002, most of which were included within transects covered in this study. For Harlequin Ducks, previous survey data published by Smith *et al.* (2001) for winters 1995-1999 and by Rodway *et al.* (2003) for 2000 were included. These data allowed a 10-year pattern in sex and age ratios to be investigated for Harlequin Ducks. The historical survey data for Harlequin Ducks relied primarily on transect counts, and covered many of the same areas as the present study.

   2.4.3   Habitat-related variation in sea duck densities and sex/age composition

   Sex and age ratio estimates derived from direct field counts are subject to bias if cohorts segregate according to habitat type. While large samples drawn from an extensive area covering all available habitats can alleviate such concerns, we felt it was important to quantify the magnitude of any distributional biases. To conduct our analyses we related geo-referenced survey data to habitat attributes described in the British Columbia Marine Ecosystem Classification (BCMEC) for the Pacific Coast of Canada (Zacharias *et al.* 1998). Specifically, we

assessed variations in sea duck densities, sex ratios, and age ratios with respect to: 1) substrate type (as categorized by BCMEC using Geological Survey of Canada sediment distribution maps), with sites classified as *hard*: bedrock, boulders, or cobble, with gravel/sand interspersed; *sand*: sand or sand/gravel; or *mud*: mud or sand/mud; 2) wind and wave exposure, categorized as *low*: protected area, fetch <50 km; or *moderate*: open sound or strait, fetch 50-500 km; and 3) depth profile (derived from bathymetric spot soundings developed by the Canadian Hydrographic Service), with classifications for *shallow*: <20 m, *photic* 20-50 m, or *mid-depth* 50-100 m.

Our statistical approach was to use Akaike's Information Criterion (AIC) to select the most parsimonious model or models among a set designed to evaluate the aforementioned relationships (Burnham and Anderson 2002). In the most fully parameterized model used in each analysis, substrate type, exposure, and depth were all included as potential explanatory variables. Less parameterized models, which considered all possible combinations of these variables (treated as main effects) were evaluated, as was a null model, for a total of 8 models in each candidate set (Table 2.4.3). Generalized linear models were used to calculate likelihood ratios for our AIC analyses, with a normal error distribution used for models predicting sea duck densities and a binomial error distribution when investigating sex and age ratios. To elucidate our results, we present ΔAIC_c and ω_i values, where ΔAIC_c is a sample-size corrected estimate of the difference in model fit between the current model and the best supported model, and ω_i is the weight of a given model, calculated as its likelihood relative to all of the models tested (Burnham and Anderson 2002). Potential explanatory variables could appear in multiple models; therefore, we made an additional calculation for $\Sigma\omega_i$ for each variable. For example, $\Sigma\omega_{substrate}$ would be the summed total of Akaike weights for the 4 models [(a) SUB, EXP, DEP; (b) SUB, EXP; (c) SUB, DEP; (d) SUB] considering substrate as a potential predictor of male age ratio for a given species. $\Sigma\omega_i$ values were useful for quantifying the amount of support for each variable when several models had low ΔAIC_c scores.

Table 2.4.3. Variables considered in models relating sea duck densities, sex ratios, and age ratios to habitat variables.

Model Notation	Predictor variables considered	$K^{\dagger}$
SUB, EXP, DEP	Substrate, Exposure, Depth	7
SUB, EXP	Substrate, Exposure	5
SUB, DEP	Substrate, Depth	6
EXP, DEP	Exposure, Depth	5

DEP	Depth	4
Null	None	2

†Number of parameters in the model.

3   RESULTS

3.1   Sea duck densities

Surf and White-winged Scoters were the two most numerous species in our survey transects, with a minimum of 1500 individuals observed per species per year (Table 3.1). The largest abundance estimate for a single species within any survey transect was for White-winged Scoters in Semiahmoo Bay, where 620 birds were observed on February 4, 2003. The maximum count for Surf Scoters occurred on the same day, in the same location, with 490 Surf Scoters observed. Black Scoters numbers also were relatively high in our survey transects, with >750 individuals counted each year and a linear density estimate of 14.4 ± 1.3 birds km^{-1}. Approximately 90% of all survey transects contained at least one Surf Scoter, while 60% had at least one White-winged Scoter and 54% at least one Black Scoter (Table 3.1).

Harlequin Duck linear densities were the third highest among the nine target species. Annual counts ranged from 1009 to 1287 birds, with approximately 79% of transects occupied by at least one Harlequin Duck, and the maximum count in of 111 any 1-km block (Table 3.1).

Annual counts ranged from 883-895 for Bufflehead, 387-413 for Barrow's Goldeneye, and 618-632 for Common Goldeneye. The proportion of transects occupied followed a similar pattern as overall densities for the Bucephala species, with approximately 95% of survey transects having at least one Bufflehead present, 83% at least one Common Goldeneye, and 43% at least one Barrow's Goldeneye (Table 3.1).

Table 3.1. Linear densities (birds km^{-1}), maximum numbers, and percentage of transects occupied for sea duck species[†].

Species	Birds km^{-1} ± SE	Maximum	% transects occupied
Scoters			
Black Scoter	14.4 ± 1.3	165	53.8
Surf Scoter	36.5 ± 10.5	490	89.5
White-winged Scoter	36.9 ± 0.8	620	59.9
Harlequin Duck			
Harlequin Duck	20.7 ± 0.1	111	79.1
Bufflehead and Goldeneye			
Barrow's Goldeneye	7.3 ± 1.1	88	43.2
Bufflehead	16.2 ± 1.8	73	94.7
Common Goldeneye	11.4± 1.2	70	83.0
Mergansers			
Common Merganser	0.9 ± 0.1	26	25.5
Red-breasted Merganser	4.5 ± 0.5	34	69.7

[†]Linear densities and the percentage of transects occupied were averaged across years. 49 1-km blocks were surveyed in 2003 and 62 1-km blocks in 2004.

Red-breasted Mergansers counts ranged from 241-247 per year, with individuals exhibiting a highly dispersed distribution pattern. Approximately 70% of transects were occupied by at least one individual. In contrast, Common Merganser were low, averaging approximately 50 birds per year and 26% transect occupancy. Four Hooded Mergansers were observed in our survey transects during 2004, none were observed in 2003.

3.2   Sex and age ratios

3.2.1   Scoters

Black and Surf Scoter populations were the most heavily male-biased of the sea duck species surveyed (Table 3.2.1). Overall, males outnumbered females 3.4 to 1 among Black Scoters and 2.3 to 1 among Surf Scoters. The proportion of individuals that were adult male was identical for the two species, with the ratio of $M_{ADU}:(M_{TOTAL} + F_{TOTAL})$ estimated as 0.64 ± 0.02 for Black Scoters and 0.64 ± 0.04 for Surf Scoters. Black Scoter flocks had a higher proportion of first year males than did Surf Scoter flocks, with $M_{1Y}:M_{TOTAL}$ ratios estimated as 0.14 ± 0.03 and 0.07 ± 0.02, respectively. Assuming a 1:1 ratio between 1Y males and females in the Strait of Georgia, female age ratios ($M_{1Y} / (F_{TOTAL} - M_{1Y})$) of 0.48 and 0.17 would be estimated for Black and Surf Scoters, respectively. The large difference in this last ratio when compared to the 1Y male to total male ratio indicates that these estimates are highly sensitive to small differences in 1Y male estimates.

Table 3.2.1. Sex and age ratio estimates for scoters in the Strait of Georgia during winter 2003 and 2004.

Species	Year	Total	F_{TOTAL}	M_{TOTAL}	M_{ADU}	M_{1Y}	M_{ADU}: Total	M_{1Y}: M_{ADU}	F_{1Y}: F_{ADU}
Black Scoter	2003	719	197	522	446	76	0.62	0.17	0.63
	2004	811	223	588	531	57	0.65	0.11	0.34
Surf Scoter	2000[†]	1221	442	779	680	100	0.56	0.15	0.29
	2001[†]	1316	422	894	833	62	0.63	0.07	0.17
	2002[†]	1212	379	833	629	72	0.52	0.11	0.23
	2003	2009	639	1370	1288	82	0.64	0.06	0.15
	2004	1613	512	1101	1020	81	0.63	0.08	0.19
White-winged Scoter	2003	1848	n/a	n/a	n/a	n/a	n/a	n/a	n/a
	2004	2235	n/a	n/a	1180	n/a	0.53	n/a	n/a

[†]Data published by Iverson *et al.* (2004) for surveys conducted from 2000-2002 in the Strait of Georgia.

White-winged Scoter populations were much less adult male-biased than were Black or Surf Scoter populations. In 2004, the only year for which sex ratio data were collected, the proportion of White-winged Scoters that were adult male was 0.53 (Table 3.2.1).

Annual variation in sex ratios was not statistically significant for Black Scoters during the two years of study (W = 2.0, d.f. = 1, P = 0.16), however, variation in age ratios was significant (W = 6.1 d.f. = 1, P = 0.01). For Surf Scoters, we incorporated previously published data (Iverson *et al.* 2004) in our analyses of annual variation in sex and age ratios. Annual estimates for proportion adult male ranged from 0.49-0.62, while male age ratios ranged from 0.06-0.13. Generalized linear model ANOVA results indicated both of these differences were statistically significant (sex: W = 22.4, d.f. = 4, P < 0.001; male age: W = 31.2, d.f. = 4, P < 0.001). Figure 3.2.1 depicts the five year patterns in sex and age composition for Surf Scoter flocks in the Strait of Georgia.

Figure 3.2.1. Annual variations in sex and male age ratios for Surf Scoters wintering in the Strait of Georgia. The figure includes data collected by Iverson *et al.* (2004) during winters 2000-2002.
3.2.2 Harlequin Duck

Harlequin Duck populations also were male-biased. The overall sex ratio was 1.4 males per female and the proportion adult male was 0.53 ± 0.01 for the two years of survey data combined. The ratio of first year to adult males ranged from 0.07 to 0.10. Assuming a 1:1 sex ratio among immature birds, a female age ratio (M_{1Y} / (F_{TOTAL} - M_{1Y})) of 0.11:1 was calculated.

Generalized linear model ANOVA results suggested that annual variation in Harlequin Duck sex ratios was not statistically significant (W = 6.8, d.f. = 7, P = 0.45). Estimates for the proportion adult male in the population, which include data collected in this study and those reported by Smith *et al.* (2001) and Rodway *et al*. (2003), ranged from 0.52-0.56 (Table 3.2.2). Annual variation in male age ratios was statistically significant (W = 24.6, d.f. = 7, P < 0.001), with estimates ranging from 0.04-0.10 (Table 3.2.2). Figure 3.2.2 depicts a ten year pattern in sex and age composition for Harlequin Duck populations in the Strait of Georgia

Table 3.2.2. Sex and age ratio estimates for Harlequin Ducks in the Strait of Georgia during winter 2003 and 2004.

Species	Year	Total	F_{TOTAL}	M_{TOTAL}	M_{ADU}	M_{1Y}	M_{ADU}: Total	M_{1Y}: M_{ADU}	F_{1Y}: F_{ADU}

[†]Data published by Smith *et al.* (2001) for surveys conducted from 1995-1999 and Rodway *et al.* (2003) in 2000 in the Strait of Georgia.

Figure 3.2.2. Annual variation in sex and male age ratios for Harlequin Duck populations wintering in the Strait of Georgia. The figure includes historical data collected by Smith *et al.* (2001) and Rodway *et al.* (2003).
3.2.3 Bufflehead and Goldeneye

Common and Barrow's Goldeneye populations had similar adult male proportions, with overall estimates of 0.57 ± 0.03 and 0.55 ± 0.02, respectively. The proportion adult male Bufflehead was 0.50. Male age ratios were higher among Common Goldeneye than Barrow's Goldeneye, with M_{1Y}:M_{TOTAL} estimates of 0.12 ± 0.02 and 0.07 ± 0.01 in the Strait of Georgia during winter 2003 and 2004, respectively. The overall sex ratio for Common Goldeneye was 2.0:1, whereas for Barrow's Goldeneye it was 1.5:1. Female age ratios (M_{1Y} / (F_{TOTAL} - M_{1Y})) were calculated as 0.24 and 0.11 for Common and Barrow's Goldeneye, respectively.

Annual variation in Barrow's Goldeneye adult male proportions was not significant (W = 1.2, d.f. = 1, P = 0.28, Table 3.2.3), however, differences in Common Goldeneye adult male proportions were significant (W = 4.6 d.f. = 1, P = 0.03, Table 3.2.3). Variation in male age ratios was not significant for either goldeneye species (Common Goldeneye: W = 1.0, d.f. = 1, P = 0.32; Barrow's Goldeneye: W = 0.4, d.f. = 1, P = 0.50).

Table 3.2.3. Sex and age ratio estimates for Bufflehead and Goldeneye in the Strait of Georgia during winter 2003 and 2004.

Species	Year	Total	F_{TOTAL}	M_{TOTAL}	M_{ADU}	M_{1Y}	M_{ADU}: Total	M_{1Y}: M_{ADU}	F_{1Y}: F_{ADU}

Merganser	2004	247	n/a	n/a	103	n/a	0.42

3.3   Habitat related variation in species densities and sex/age composition

3.3.1   Sea duck density

Variation was apparent in sea duck densities across habitat types. Figure 3.3.1(a-c) illustrates the relationships between sea duck linear densities and the three habitat variables we investigated. Surf and White-Winged Scoter densities tended to be higher in areas with low exposure to wind and wave and in shallower areas. Black Scoter were much less numerous than Surf and White-winged Scoters in these areas, but occurred in similar numbers to the other scoters species in more exposed transects and transects with hard substrates. Harlequin Ducks were unique among sea ducks in exhibiting their highest densities over hard bottom areas, in areas that were more exposed to wind and wave, and in areas where the maximum depth was greater. Barrow's Goldeneye densities tended to be lower in sandy bottom transects and more exposed transects, while Common Goldeneye and Bufflehead densities differed relatively little among habitat types. Merganser densities were not sufficiently high to detect habitat-specific distributional patterns in this study.

Figure 3.3.1. Linear densities of sea duck species according to (a) substrate type, (b) exposure, and (c) depth, in the Strait of Georgia.
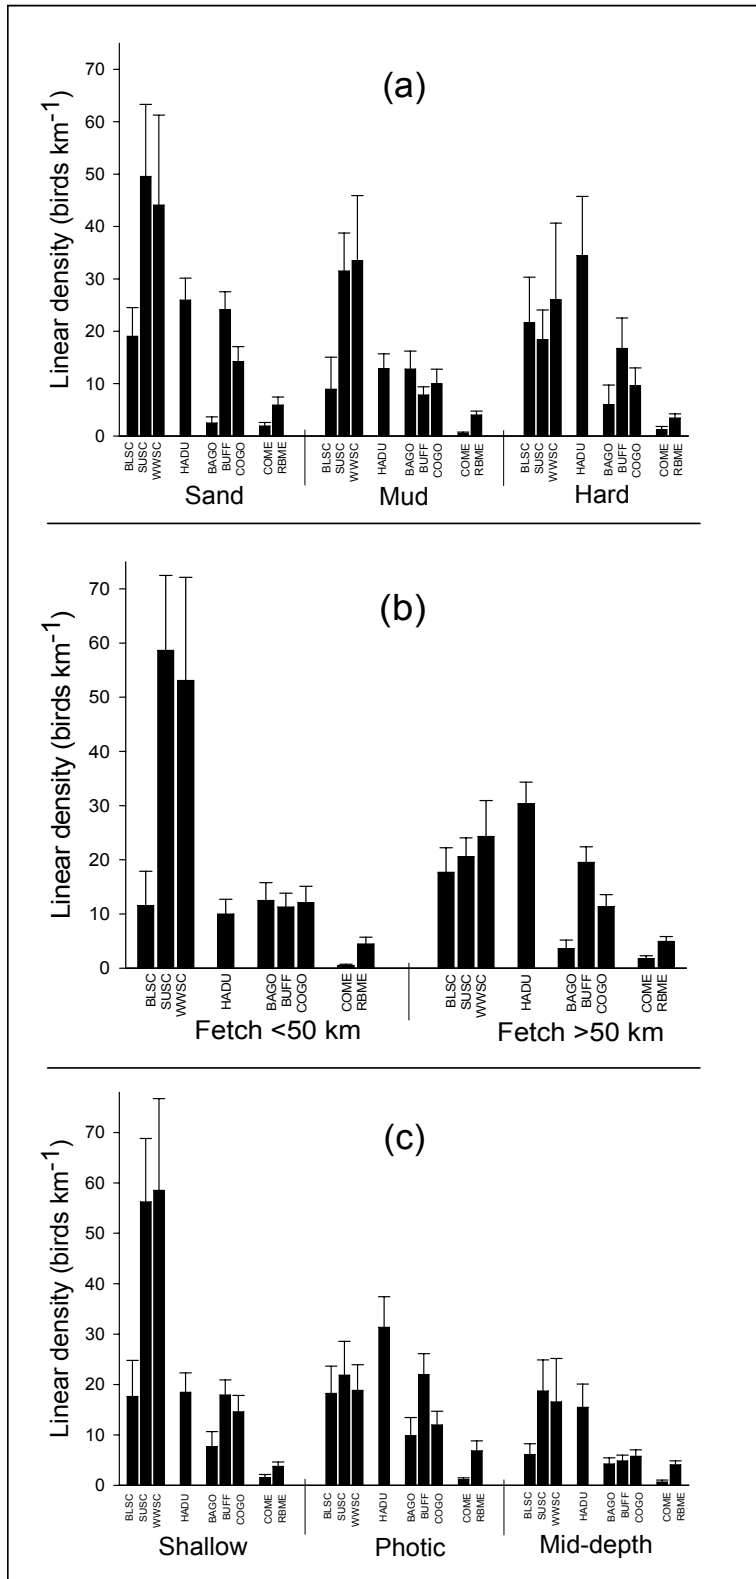

3.3.2   Scoters

There was some evidence of habitat-related segregation by sex and age class among scoters. The generalized linear model best fitting the data for Black Scoter sex ratio included exposure and depth as main effects (Table 3.3.2a). This model had an Akaike weight of 0.50. There also was some support for models considering depth [(DEP): $\Delta AIC_c = 1.81$, $\omega_i = 0.20$] and the general model [(EXP, DEP, SUB): $\Delta AIC_c = 1.95$, $\omega_i = 0.19$]. $\Sigma\omega_i$ estimates for substrate, exposure, and depth were 0.27, 0.73, and 0.95, respectively. Model averaged means for Black Scoter adult male proportions tended to be highest in mid-depth and moderately exposed survey transects, and lowest in protected, photic, and sandy substrate sites (Figure 3.3.2). With respect to age-related habitat segregation, substrate appeared to be the most important predictor of male age ratio, with model averaged male age ratio estimates highest over sandy substrates (Figure 3.3.2). The model best fitting the data (DEP, SUB) had an Akaike weight of 0.49. There were two other models with $\Delta AIC_c < 2.5$, both of which included substrate as a predictor variable (Table 3.3.2a). $\Sigma\omega_i$ estimates for substrate, exposure, and depth were 0.99, 0.27, and 0.67, respectively.

Table 3.3.2a. Akaike scores (ΔAIC_c) and weights (ω_i) for candidate models explaining variation in Black Scoter sex and age ratios according to habitat type.

Sex ratio				Age ratio			
Model[a]	K[b]	ΔAIC_c[c]	ω_i[d]	Model[a]	K[b]	ΔAIC_c[c]	ω_i[d]

[a] Explanatory variables in general linear models
[b] Number of estimable parameters
[c] Difference between AIC_c of the current model versus the best supported model
[d] Relative likelihood of a model among the 8 tested

Surf Scoter distributions also were not random with respect to habitat. Substrate, exposure, and depth profile all were supported as predictors of surf scoter sex ratios, with the model best fitting the data containing all three variables [(SUB, EXP, DEP): $\omega_i = 0.80$]. $\Sigma\omega_i$ estimates were 0.98, 1.00, and 0.80, for substrate, exposure, and depth, respectively. Model averaged parameter estimates for Surf Scoter adult male ratios tended to be highest over sandy substrates, in areas with higher exposure to wind and waves, and when depth profiles were deepest (Figure 3.3.2). With respect to age-related habitat segregation, two models had a high

Figure 3.3.2. Habitat-related variation in the sex and age composition of Scoter flocks. Grey bars denote ratios of adult male to total birds, black bars ratios of first year males to adult males, and dashed lines overall means.
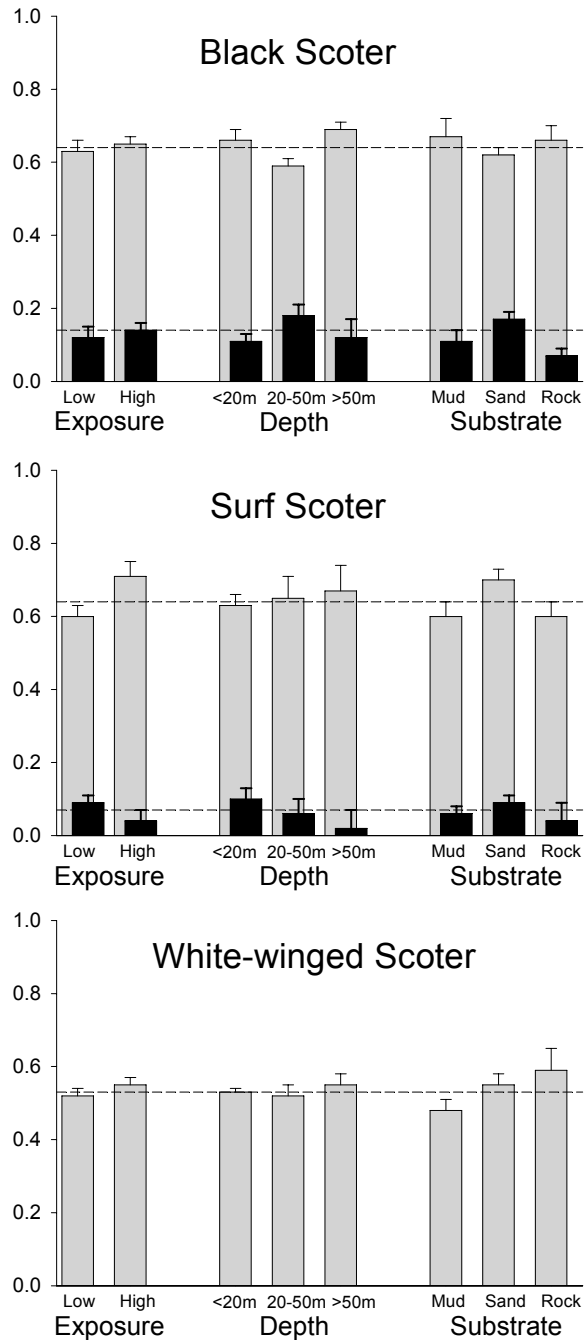

degree of support. The best fitting included all three habitat attributes as main effects, while the next included exposure and depth and had ΔAIC_c = 0.49. Akaike weights for the two models were 0.55 and 0.45, respectively (Table 3.3.2b). $\Sigma\omega_i$ estimates for the models that included substrate, exposure, and depth were 0.56, 1.00, and 1.00, respectively. Model averaged parameter estimates for Surf Scoter age ratios were highest in mid-depth, low exposure, and sandy habitats (Figure 3.3.2).

With respect to sex-related habitat associations among White-winged Scoters, several models fit the data similarly well. The models that best fit the data (SUB, DEP) had Akaike weight of 0.36, while the next best fitting models (SUB, EXP, DEP) and (SUB) had ΔAIC_c scores of 0.14 and 1.15, and ω_i = 0.34 and 0.20, respectively (Table 3.3.2c). $\Sigma\omega_i$ estimates for substrate, exposure, and depth were 0.98, 0.42, and 0.70, respectively. Model averaged adult male proportions tended to be highest over hard bottom substrates, and in areas with steeper depth profiles (Figure 3.3.2).

3.3.3 Harlequin Ducks

Some support was evident for exposure as a predictor of sex and age ratios of Harlequin Ducks. With respect to sex ratios, the model best fitting the data included exposure as the only main effect (Table 3.3.3). This model had an Akaike weight of 0.39. However, the null model also was well supported, with ΔAIC$_c$ = 0.24 and ω$_i$ = 0.35. Σω$_i$ estimates for exposure, depth, and substrate were 0.52, 0.16, and 0.13, respectively. Model averaged parameter estimates for adult male proportions tended to be highest in less exposed survey transects (low: 0.55 ± 0.1 vs. moderate: 0.49 ± 0.2; Figure 3.3.3). With respect to age-related habitat segregation, exposure also was the only main effect in the model best fitting the data. This model had an Akaike weight of 0.47. Models including exposure and substrate [(EXP, SUB): ΔAIC$_c$ = 1.79, and ω$_i$ = 0.19] and exposure and depth [(EXP, DEP): ΔAIC$_c$ = 1.91, and ω$_i$ = 0.18] also received some support (Table 3.3.3). Σω$_i$ estimates for exposure, depth, and substrate were 0.91, 0.27, and 0.30, and model averaged parameter estimates for male age ratios tended to be higher in moderately exposed areas, in rocky areas, and in areas with deeper maximum depths (Figure 3.3.3).

3.3.4   Bufflehead and Goldeneye

For Barrow' Goldeneye, the habitat model best fitting the data included exposure and substrate as predictors of the proportion adult male (Table 3.3.4a). This model had an Akaike weight of 0.43. There also was some support for the null model (ΔAIC_c = 1.45, ω_i = 0.21), and a model including substrate as a main effect [(SUB): ΔAIC_c = 2.170, ω_i = 0.14]. $\Sigma\omega_i$ estimates for substrate, exposure, and depth were 0.66, 0.59, and 0.13, respectively. Barrow's Goldeneye adult male proportions tended to be lowest in moderately exposed survey transects and those with muddy substrates (Figure 3.3.4). With respect to age-related habitat segregation, exposure and substrate both appeared to be important variables. The model best fitting the data [EXP] had an Akaike weight of 0.37. However, models which included substrate ([SUB]: ΔAIC_c = 1.80, ω_i = 0.15), substrate and exposure ([SUB, EXP]: ΔAIC_c = 2.14, ω_i = 0.13) and the null model (ΔAIC_c = 2.18, ω_i = 0.13) also received support (Table 3.3.4a). $\Sigma\omega_i$ estimates for substrate, exposure, and depth were 0.40, 0.60, and 0.22, respectively. Barrow's Goldeneye male age ratios tended to be highest in more exposed transects, and over sandy and rocky substrates (Figure 3.3.4).

Figure 3.3.4. Habitat-related variation in the sex and age composition of Bufflehead and Goldeneye flocks. Grey bars denote ratios of adult male to total birds, black bars ratios of first year males to adult males, and dashed lines overall means.
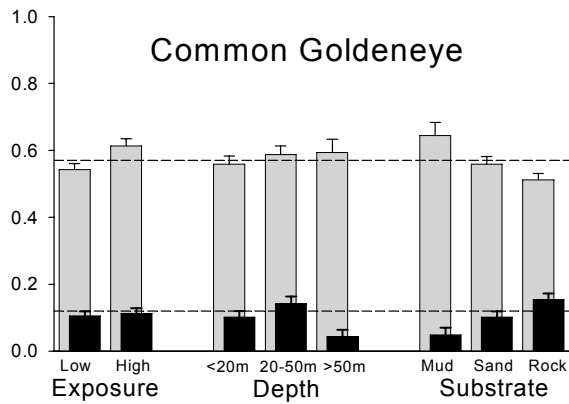

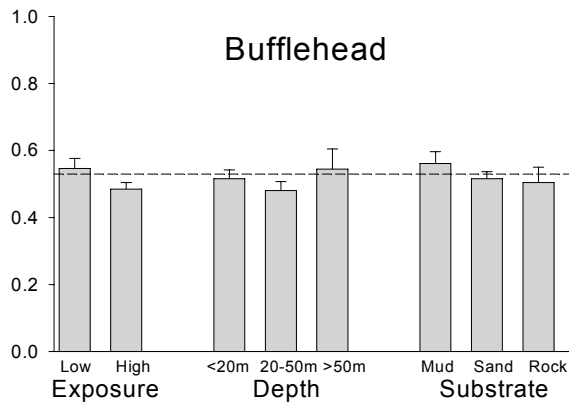

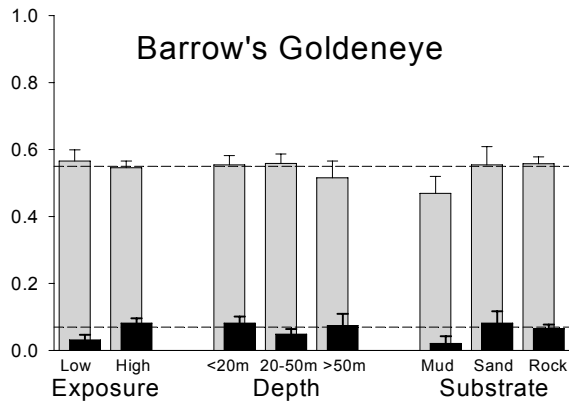

For Bufflehead, several models had similar fit with respect to sex-specific habitat associations. The best fitting model included exposure as a main effect and had an Akaike weight of 0.35. The null model also was supported, with ΔAIC_c = 0.90 and ω_i = 0.22. Model weights also were ≥ 0.10 for models considering substrate ([SUB]: ΔAIC_c = 1.56, ω_i = 0.16) and substrate and exposure ([SUB, EXP]: ΔAIC_c = 2.57, ω_i = 0.10) as main effects (Table 3.3.4b). $\Sigma\omega_i$ estimates for substrate, exposure, and depth were 0.30, 0.53, and 0.16, respectively. Model averaged adult male proportions tended to be highest over low exposure and muddy substrate transects for Bufflehead (Figure 3.3.4).

Common Goldeneye sex and age distributions also were not random with respect to habitat. With respect to sex ratios, the model best fitting the data included substrate and depth as predictors ([SUB, DEP]: ω_i = 0.67). The most fully parameterized model also had some support ([SUB, EXP, DEP]: ΔAIC_c^c = 2.07, ω_i = 0.24). $\Sigma\omega_i$ estimates for substrate, exposure, and depth were 1.00, 0.27, and 0.90, respectively. Common Goldeneye adult male ratios tended to be highest in deep water transects, in muddy substrate transects, and in more exposed transects (Figure 3.3.4). With respect to age-related segregation, the model that included substrate and exposure had the best fit to the data ([SUB, EXP]: ω_i = 0.73; Table 3.3.4c). $\Sigma\omega_i$ estimates for substrate, exposure, and depth were 1.00, 0.84, and 0.14, respectively. First-year male Common Goldeneye ratios tended to be highest in shallow and rocky transects (Figure 3.3.4)

3.3.5 Mergansers

For Red-breasted Mergansers, the model best fitting the data indicated that exposure and depth were significant predictors of the proportion adult male ([EXP, DEP]: ω$_i$ = 0.37; Table 3.3.5). Support also was evident for the model which considered exposure as the sole main effect ([EXP]: ΔAIC$_c$ = 0.94 and ω$_i$ = 0.23). Σω$_i$ estimates for substrate, exposure, and depth were 0.27, 0.74, and 0.52, respectively. The model averaged parameter estimates for adult male proportions tended to be higher in more exposed transects and deeper water transects. Habitat-related variation in sex ratios was not analyzed for Common Mergansers due to sample size considerations.

4 CONCLUSIONS

Given the lack of data available for monitoring sea duck populations, information as basic as the sex and age structure of wintering flocks is valuable for management purposes. The mid-winter surveys described in this report provide important baseline information on the density and composition, as well as the patterns of annual variation and habitat use, for a suite of species of conservation concern. Several findings are of particular interest and their biological implications and associated measurement considerations are discussed below.

The most striking finding in this study was the strength of the male-bias in adult sex ratios, particularly among Black and Surf Scoters. Adult sex ratios of most waterfowl are skewed toward males (Bellrose *et al.* 1961), and there are several different hypotheses to explain the phenomenon. The major cause is thought to be higher mortality rates experienced by females during the breeding season (Johnson *et al.* 1992, Sargeant and Raveling 1992). Hunting mortality rates also have been shown to differ between the sexes, which can influence sex ratios among adults (Johnson and Sargeant 1977). Among diving ducks, inter-sexual competition during the non-breeding season has been proposed as another mechanism whereby adult female mortality might exceed that of males. Male diving ducks tend to be behaviourally dominant to females, and in some instances exclude them from preferred feeding habitats during winter (Nichols and Haramis 1980, Owen and Dix 1986, Alexander 1987). The magnitude of the male-bias in adult sex ratios tends to be greater among diving ducks than dabbling ducks, with Canvasbacks (*Aythya valisineria*) and Common Pochards (*Aythya ferina*) providing two of the more extreme examples, exhibiting adult sex ratios of two or three males for every female in some wintering areas (Haramis *et al.* 1985, Owen and Dix 1986). Our data suggest some similarity between sea ducks and diving ducks in this regard. Among the five species for which adult sex ratios could be readily estimated, Surf and Black Scoters had the most skewed adult sex ratios, with estimates of 2.3 and 3.5 males per female respectively. Harlequin Ducks were the least skewed, with 1.4 males per female, while the two goldeneye species were intermediate, with adult sex ratios estimated as 1.5 males per female for Barrow's Goldeneye and 2.0 males per female for Common Goldeneye. For White-winged Scoters, Bufflehead, and Common Mergansers, the proportion adult male ranged from 50-55%. These proportions were similar to those estimated for the Harlequin Duck, and assuming similar age ratios, would suggest adult sex ratios of 1.3 to 1.5 males per female. Red-breasted Mergansers had a lower proportion adult male than the other eight species, with only 42% categorized as adult male by plumage appearance.

A second important finding in this study was the low proportion of immature birds. Male age ratios ($M_{1Y}:M_{TOTAl}$) ranged from 0.07 for Surf Scoters and Barrow's Goldeneye to 0.14 for Black Scoters. This result was not surprising, given the high adult survival-low annual productivity life history strategy characteristic of sea ducks. However, uneven sex ratios and age-structured populations have important implications when translating census data to measurements of effective population size. Taking Common Goldeneye as an example, in 2004 a total of 632 individuals were observed within our survey transects, of which 200 were female. Assuming equivalent numbers of first year males and females, an age of first breeding of 2 years, and sub-adult survival rates of ~70%, the number of females of breeding age in our mid-winter count would have been approximately:

$$N_{BreedingAgeFemale} = N_{TotalFemales} - N_{1YFemales} - N_{2YFemales}$$
$$= 200 - 54 - (0.7 * 54)$$
$$= 108$$

This estimate does not account for annual variation in productivity or survival, but does illustrate the degree to which the number of potential breeding pairs can be overestimated if population sex and age structure are not taken into account. In this example, the effective population size would only be about 34% of the census count.

Given the age ratios we estimated, a natural question is to what degree do they match the expected, given the survival rates estimated for various sea duck species? In the simplest of demographic models, where the population growth rate is maintained at λ = 1 and immigration is ignored, birth and death rates must be in balance. While reliable estimates of annual survival are not available for all sea duck species, and geographic variation is likely, current estimates range from 60-90%, depending upon species, sex, age, and methodological approach (Ludwichowski *et al.* 2002, Eadie *et al.* 1995, Savard and Eadie 1989, Cooke *et al.* 2000, Kehoe *et al.* 1989). Robertson (*in press*) addressed the question of what survival rates and juvenile/adult ratios are needed to maintain stable populations for Harlequin Ducks using a matrix-based age-structured population model, and concluded that there is a significant mismatch between recruitment, as estimated using winter age ratios, and survival. Survey data indicate that Harlequin Duck populations in the Pacific Flyway are not undergoing the declines such a mismatch would indicate (*S. Boyd, unpubl. data*), and one must question whether recruitment, survival, or both are being underestimated using existing methodologies.

There is a possibility that age ratios were underestimated using direct visual counts on wintering areas. Previous research on Harlequin Ducks showed potential for misidentification of

first year males when using boat-based rather than shore based surveys (Rodway *et al.* 2003). Rodway and coauthors also discovered a tendency for first year males to be further from shore than adult males, and used a correction factor to account for sampling bias. Many of the differences in plumage appearance that are used to distinguish cohorts are subtle, and several important considerations must be made when evaluating the ability of researchers to accurately identify them. The first pertains to moult timing. When newly fledged male sea ducks first arrive on non-breeding areas they exhibit cryptic plumages that are very similar to those of adult females. The timing of moult from the first basic into the first alternate plumage is somewhat variable, which is why our survey was timed for late January-early February—the period when plumage differences were shown to be most pronounced for Surf Scoters (Iverson *et al.* 2003). However, we can not eliminate the possibility that some portion of early moulting first year males progress to the point where they are indistinguishable from adult males, or that some late moulting birds are indistinguishable from females, using field observations alone. When birds are in hand, the differences are clear (e.g. Smith *et al.* 2001, Iverson *et al.* 2003), however, at a distance of 100 m through a spotting scope, traits such as belly and body plumage coloration, the presence or absence of facial markings, and bill coloration and shape are more difficult to diagnose with certainty. As yet, a methodology for determining the proportion of misidentified birds has not been developed. Finally, it should be noted that some confusion was encountered in our survey with respect to bill coloration among Black Scoters. Originally, it was assumed that females had no yellow coloration on their bills, however subsequent evaluation of birds captured in a telemetry study showed that adult females (>2Y) often have yellow areas on the top of their bills. One of the primary means of identifying first year male Black Scoters was the existence of a bulbous yellow enlargements similar to those of adult males, and it is likely that some females were classified as first year males when other diagnostic traits such as breast and belly coloration and the presence of black and brown mottled body feathers were not seen.

For the species we investigated, some segregation of the sex and age classes among habitats was apparent. However, the magnitude of distribution biases was generally quite small. The most pronounced effects were evident for Surf Scoters—where adult male proportions tended to be higher in transects with sandy substrates and those with higher exposure to wind and waves, and male age ratios tended to be higher in transects of shallower depth and those with lower exposure to wind and wave; Black Scoters—where adult male proportions were highest in more exposed transects; Harlequin Ducks—where male age ratios were highest in more exposed sites; and Common Goldeneye—where adult male proportions were highest in exposed transects. While habitat-related variation was minimal, and sampling bias could be

minimized by ensuring large samples are collected representatively from available habitats, some larger distributional considerations remain. For species such as Black Scoters, Surf Scoters, and Common Goldeneye, for which sex-ratios were heavily male-biased, and Red-breasted Mergansers, for which females outnumbered males; the possibility that the sexes are geographically segregated must be considered. Such patterns are not uncommon among migratory bird species (Ketterson and Nolan 1976; Cristol *et al.* 1999), and the ecological implications include differential exposure to selective pressures, such as inclement weather or predation. Pairing chronology and the durability of pair bonds also may be affected, which in turn influences gene flow and population structure (Cooke *et al.* 2000). With respect to age-related differences in non-breeding distribution an important question arises with respect to defining population units. If immature birds do not winter in the same locations as their parents, then considerable complexity is added when attempting to use winter age ratios as an index of recruitment. The spatial scale at which populations would have to be monitored would become prohibitively large, and the power of inference at smaller spatial scales, like the Strait of Georgia would be limited.

Data on the sex and age composition of sea duck populations in different wintering areas is extremely sparse. Iverson *et al.* (2004) used a volunteer survey to investigate latitudinal patterns in sex and age ratios in the Pacific Flyway and found no evidence that larger numbers of females wintered in more southerly areas. However, sample sizes were small, and recent studies initiated in Baja, Mexico, suggest sex ratios may be closer to 1:1 (D. Rizzolo and T. Bowman personal comment). With respect to pairing chronology, waterfowl that pair late tend to exhibit greater segregation of the sexes and more disparate sex ratios during the non-breeding season compared to species that pair early (Hepp and Hair 1984). Among the species we investigated, Harlequin Ducks are the best studied in this regard. Harlequin Duck pairing occurs early, with >50% of females being paired by December (Robertson *et al.* 1998). Moreover, it is common for females to reunite with the same male, with the repairing rate approaching 100% if both partners are known to have survived and returned to the same wintering ground (Gowans *et al.* 1997, Robertson *et al.* 1998). There is some evidence for early pairing among Barrow's Goldeneye, particularly among previously paired birds (Savard 1985). In contrast, Kahlert *et al.* (1998) found that male and female Red-breasted Mergansers remain segregated for most of the winter, with pairs only beginning to separate from flocks in early spring. Among the other sea duck species, the chronology of pair formation is less certain. Brown and Fredrickson (1997) suggested that because White-winged Scoters are among the latest migrating and nesting waterfowl, pairing during migration seems likely. Our own observations during winter in the

Strait of Georgia, however, suggest that a high proportion of adult females behave as if paired during early winter. White-winged Scoters tend to form loose flocks during early winter, with male-female pairs moving in close proximity, diving synchronously, and males defending a buffer space around their presumed mate. In contrast, Black and Surf Scoters typically form larger, denser flocks, within which it impossible to recognize pairs with any certainty. Courtship activities occur all winter, but intensify during spring migration.

There is a clear need for new techniques to monitor the health of sea duck populations. Traditional methods have not worked well for most species because they breed in low densities in remote portions of the continent. The primary conservation implication of our study is that winter sex and age ratio surveys can be a reliable, inexpensive means of gathering data for an important demographic index. However, several important considerations must be made before incorporating such data in population models. These include: 1) ensuring that age ratios are not underestimated, owing to the difficulty of visually distinguishing sex and age cohorts; 2) determining the validity of using male age ratios to infer female age ratios and ensuring that composition estimates are representative of the population as a whole, and 3) determining the spatial scale at which true populations are being studied, in order to ensure that inference about the survival and recruitment are valid. To answer these questions, further study is required. However, such an effort appears warranted to better equip us to understand declining sea duck populations and manage them for sustainability.
