## LIST OF SYMBOLS USED

C = bulk compressibility of disposal formation, in vol/vol/atmosphere
$h=$ thickness of the disposal formation (effective thickness), in cm ( ft )
$h_{c}=$ thickness of confining beds, in $\mathbf{c m}(f t)$
I = natural hydraulic gradient, dimensionless
$P_{f}=$ natural fluid pressure in disposal formation, at well bore, in psi (atm)
$P_{f r}=$ pressure loss due to friction of moving fluid inside well tubing, in psi (atm)
$P_{0}=$ pressưre exerted by weight of saturated overburden material, in psi (atm)
$P_{w}=$ pressure exerted by weight of waste column in injection well, in psi (atm)
$P_{i}=$ well-head pressure during injection of waste fluid, in psi (atm)
$\Delta P=$ increase in pressure in disposal formation, at the well bore, as a result of waste injection, in psi (atm)
$q_{\mathbf{t}}=$ injection rate, in "dimensionless units"
$q_{T}=$ injection rate, in $\mathrm{cm}^{3} /$ second (US gal/minute)
$Q_{t}=$ injected volume, in "dimensionless units"
$Q_{T}=$ injected volume, in $\mathrm{cm}^{3}$ (US gallons)
$r=$ distance from injection well, in multiples of well radius $r_{w}$
$r_{1}=$ distance from injection well, in cm (feet)
$r_{\mathbf{e}}=$ radius of cylinder of injected waste in subsurface, in km (miles)
$r_{t}=$ radius of injection tubing (or casing), in cm (inch)
$r_{w}=$ well radius; in cm (inch)
$\mathrm{t}=$ time, in dimensionless units
$\mathrm{T}=$ time in seconds
$T_{e}=u s e f u l ~ l i f e ~ o f ~ w a s t e-i n j e c t i o n ~ i n s t a l l a t i o n, ~ y e a r s ~$
$\mathbf{T}_{\mathbf{t}}=$ time needed for waste to become "harmless" (if at alll, years
$V=$ velocity of fluid movement, in cm /year ( $\mathrm{ft} /$ year)
$\mathbf{Z}=$ depth of top of disposal interval below surface, in meters (feet)
$Z_{f}=$ height of static formation-water column above top of disposal interval, in meters (feet)
$Z_{w}=$ height of waste water column above top of disposal interval, in meters (feet)
$\phi=$ porosity of the disposal formation, expressed as a fraction
$\phi_{c}=$ porosity of confining beds, expressed as a fraction
$\phi_{0}=$ average porosity of the overburden, expressed as a fraction
$\kappa=$ permeability of disposal formation, in darcys
$K_{c}=$ permeability of confining beds, in darcys
$\mu=$ viscosity of waste fluid, in centipoises
$\rho_{\mathrm{f}}=$ density of natural fluid in disposal formation, in $\mathrm{g} / \mathrm{cm}^{3}$
$\rho_{\mathrm{fo}}=$ density of natural fluids in overburden (average), in $\mathrm{g} / \mathrm{cm}^{3}$
$\rho_{\text {mo }}=$ density of mineral grains in overburden (average), in $\mathrm{g} / \mathrm{cm}^{3}$
$\rho_{0}=$ average density of overbürden, in $\mathrm{g} / \mathrm{cm}^{3}$
$\rho_{w}=$ density of waste fluid, in $\mathrm{g} / \mathrm{cm}^{3}$

# Subsurface Disposal of Waste in Canada - II Disposal-Formation and Injection-Well Hydraulics 

R. O. van Everdingen

## INTRODUCTION

An adequate understanding of injection-well and disposal-formation hydraulics is a prerequisite for the formulation of criteria for the selection of sites and formations for subsurface disposal of liquid wastes. It is also needed for any evaluation of the subsurface wastedisposal potential of a larger region. Correct interpretation of injection-well performance is impossible without such knowledge (van Everdingen and Freeze, 1971).

Pressure build-up in the disposal formation, as a result of waste injection, may cause reactivation of abandoned and inadequately plugged oil, gas or water wells, even if these do not penetrate the,confining beds. Pressure build-up will also lead to an increased discharge rate from the disposal formation, whether from outcrops or through leaky confining bedss. The salinity of the discharge may increase gradually, and it can be expected that eventually waste material will appear in the discharge area. The latter will take place even if injection is discontinued. It can further be expected that waste material (or waste-derived material) will be discharged over a period of time that is appreciably longer than the period of operation of the injection well.

Most of the equations used at present to describe pressure build-up in a disposal formation during waste injection, or the movement of waste through such a formation, imply a number of simplifying assumptions. These generally include: a homogeneous disposal formation having isotropic permeability and infinite areal extent, impermeable confining beds, and permeability and porosity invariant with time. They further assume constant density and viscosity for the injected liquid, and disregard possible density differences between native and injected fluids, as well as effects of potential chemical reactions between injected liquid and formation fluids and rocks. The effect of natural hydraulic, thermal, or osmotic gradients is generally not taken into account.

Attempts to include many of the relevant variables in mathematical models have been described by Kumar and Kimbler (1970; dispersion and gravitational segregation accompanying injection of freshwater into a saline aquifer), Bredehoeft and Pinder (1971; physical-chemical description of moving groundwater in a porous medium by simultaneous solution of differential equations describing the transport of mass, energy and momentum), Henry and

Kohout (1971; streamline, velocity, temperature and salinity distribution before and during waste injection into a deep, saline, geothermally-heated aquifër), and by Whitherspoon and Neuman (1971; pressure build-up during waste injection into a multilayered aquifer/aquitard system).

Each of the above models requires the use of a high-speed digital computer. In many cases accurate values for a number of the input parameters are not available initially. They are determined through a trial-anderror process by comparison of the model results with observed distributions of pressure (salinity, temperature etc.).

To facilitate initial evaluations of waste-disposal potential, the following discussions make use of the relatively well-known nonequilibrium approach, in which the disposal formation is assumed to be homogeneous, isotropic and of infinite areal extent, with non-leaky confining beds (van Everdingen, 1968). The fluids referred to are assumed to be of uniform density, with their viscosity being a function of temperature and, to a lesser degree, of pressure. It is further assumed in the calculations that the injected liquids will not react with the formation rock or water. If such reactions do take place, both permeability and porosity will be affected.

Where necessary, an attempt is made to point out where differences between behaviour under actual and "ideal" conditions may be significant.

PRESSURE BUILD-UP vs. TIME, AT INJECTION WELL

The quantity of fluid that can be stored per unit volume of the formation is determined by the porosity of the formation; the quantity that can be stored per unit area of the formation is determined by the porosity and the thickness of the formation. The differential pressure required to inject fluid at unit rate into an initially fluid-saturated formation, is determined by formation thickness and permeability, and by fluid viscosity. The pressure-time-distance relationship is further dependent on the areal extent of the formation, the radius of the well, and the compressibilities of the fluids and the formation.

The movement of the slightly compressible fluids dealt with in subsurface disposal obeys a differential equation which states that the difference in volume of fluid flowing
in and out of an annular space between two concentric rings around a well bore is equal to the volumetric expansion of the fluids in the annulus. The fundamental equation is linear; this allows flexibility in the use of a solution; it may be multiplied or divided by a constant, or shifted in time to fit a multitude of conditions; solutions may be superposed.

Table I. Values of parameters used in examples (maximum and minimum values for some parameters).

| Parameter | Units | Example | Maximum | Minimum |
| :---: | :---: | :---: | :---: | :---: |
| C | vol/vol/atm | $0.45 \times 10^{-4}$ | - | - |
|  | vol/vol/psi | $3 \times 10^{-6}$ | - | - |

| Pfo | $\mathrm{g} / \mathrm{cm}^{3}$ | 1.1 | 1.2 | 1.0 |
| $\rho_{\text {mo }}$ | $\mathrm{g} / \mathrm{cm}^{3}$ | 2.68 | 2.87 | 2.65 |
| $\rho_{0}$ | $\mathrm{g} / \mathrm{cm}^{3}$ | 2.44 | 2.87 | 2.16 |
| $\rho_{\text {w }}$ | $\mathrm{g} / \mathrm{cm}^{3}$ | 1.2 | 1.5 | 0.8 |
| h | cm | 2000 | - | - |
|  | feet | 65.57 | - | - |
| I (horizontal) | - | 0.01 | $10^{-1}$ | $10^{-3}$ |
| $I^{1}$ (vertical) | - | 1.0 | 10 | $10^{-2}$ |
| $\kappa$ | darcy | 0.1 | 5.0 | 0.01 |
| $\mathbf{P f}_{\mathbf{f}}$ | psi | 1250 | - | - |
| $\mathrm{q}_{\mathrm{T}}$ | $\mathrm{cm}^{3} / \mathrm{s}$ | 6000 | 60,000 | 375 |
|  | USgal/min | 95.1 | 951.0 | 5.94 |
| $\mathrm{r}_{\mathbf{w}}$ | cm | 7.62 | - | - |
|  | inch | 3 | - | - |
| $r_{t}$ | cm | 3.81 | 20.32 | 1.905 |
|  | inch | $11 / 2$ | 8 | 3/4 |
| Z | m | 1000 | - | - |
|  | feet | 3280.8 | - | - |
| $\mu$ | centipoise | 0.5 | 1.0 | 0.2 |
| $\phi$ | fraction | 0.15 | 0.05 | 0.30 |
| $\phi_{\text {O }}$ | fraction | 0.1 | 0.05 | 0.35 |

In order to simplify the use of the solutions of the differential equation for the wide variety of conditions found in the natural subsurface system and for variations in
the injection rate, the time $t$, the injection rate $q_{t}$, and the injected volume $\mathrm{Q}_{\mathrm{t}}$ are expressed in "dimensionless units". Numerical values for $t, q_{t}$ and $Q_{t}$ can be derived from actual time $T$, actual rate $q_{T}$ and actual volume $Q_{T}$ through the following conversions (van Everdingen, 1968):

$$
\begin{align*}
t & =\kappa T /\left(\mu \phi C r_{w}^{2}\right)  \tag{1}\\
q_{t} & =q_{T} \mu /(2 \pi k h)  \tag{2}\\
\text { and } \mathrm{Q}_{\mathrm{t}} & =\mathrm{Q}_{\mathrm{T}} /\left(2 \pi \phi C h r_{w} 2\right) \tag{3}
\end{align*}
$$

In the following paragraphs examples of the use of these conversions and of the related pressure and volume functions will be given. A single set of values will be used in these examples (Table I); for some parameters maximum and minimum values (also listed in Table I) are selected, to demonstrate the range in magnitude of the effects of waste injection. Figure 1 enables calculation of waste density and formation water density under subsurface conditions of temperature and pressure; Figure 2 provides information on fluid viscosity at various temperatures and salt concentrations; Figure 3 presents information on the porosity, temperature, and pressure dependence of compressibility.

For the values assigned to the various parameters the following calculations can be made:

$$
\begin{aligned}
& \quad t=0.1 \mathrm{~T} /\left(0.15 \times 0.5 \times 0.45 \times 10^{-4} \times 58.06\right)= \\
& 510.327758 \mathrm{~T} \\
& \text { and } q_{t}=0.5 \times 6000 /(2 \pi \times 0.1 \times 2000)=2.387324
\end{aligned}
$$

In Table II the calculation of $t$ is carried out for times ranging from 1 day to 100 years; column 2 gives $T$ in seconds, and column 3 gives the corresponding values of $t$. The values for $P_{t}$ (cumulative pressure change; in atmospheres, at the well bore, when unit rate of injection has been maintained since time $T=$ zero, into a formation of unit thickness) are calculated from the $\mathbf{P}_{\mathbf{t}}$ function (van Everdingen, 1968):

$$
\begin{equation*}
\left.P_{t}=1 / 21 n t+0.4045 \text { (for times with } t>100\right) \tag{4}
\end{equation*}
$$

and given in column 4. Multiplication by 14.696 gives $P_{t}$ in psi (column 5); multiplication by $\mathrm{q}_{\mathrm{t}}$ produces the pressure

Table II. increase $\Delta P$ in the formation at the well bore (column 6). The results are plotted in Figure 4 (line marked " $\Delta P$ at well"). If the formation is of limited areal extent, the pressure vs. time curve will rise above that represented by equation 4, as soon as the pressure front reaches the aquifer boundaries; a constant injection rate will, in that case, result in a constant rate of pressure increase with time. A pressure fall-off test should produce a straight-line plot for observed pressure vs. the logarithm of shut-in time $\mathbf{T}_{1}$ divided by total time T . Extension of this line to the point where $T_{1} / T=1$ should give a pressure equal to the original fluid pressure in the formation. If the reservoir has a limited extent, the pressure for $T_{1} / T=1$ will be larger than the original formation pressure. The reservoir size can then be computed from the excess pressure and the total quantity of fluid injected. The results will have a significant effect on the decision on further use of the injection operation.

A sudden rapid increase in injection pressure at constant injection rate, or a decrease in injection rate at constant injection pressure, is usually indicative of plugging of the formation by suspended solids contained in the waste stream; by mobilized clay particles, or by the products of chemical or biological reactions. A gradual decrease in injection pressure or a gradual increase in the intake rate may be indicative of an increase in formation permeability through solution. A sudden decrease in injection pressure (or increase in the intake rate), on the other hand, may indicate tubing or casing failure, or the occurrence of hydraulic fracturing. The latter is dealt with in some detail later in this report. Continuous recording of both injection (tubing) pressure, and pressure in the fluid-filled annulus between injection tubing and well casing will enable early detection of pressure changes which may be indicative of trouble.

Table III. Pressure increase $\Delta \mathbf{P}$, in psi , at various times, at various distances from the injection well. $\kappa=0.1$ darcy; $\phi=15 \%$; $\mu=0.5 \mathrm{cp} ; \mathrm{h}=2000 \mathrm{~cm} ; \mathrm{r}_{\mathrm{w}}=3 \mathrm{in}(7.62 \mathrm{~cm}) ; \mathrm{q}_{\mathrm{t}}=2.3873$; $\mathrm{q}_{\mathrm{T}}=6000 \mathrm{~cm}^{3} / \mathrm{s}$.

| Time <br> (years) | Distance |  |  |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: |
|  | at well | 305 m <br> 1000 ft | $3,050 \mathrm{~m}$ <br> $10,000 \mathrm{ft}$ | $30,500 \mathrm{~m}$ <br> $100,000 \mathrm{ft}$ |  |
|  | 426.5 | 135.5 | 55.14 | 0.448 <br> 10 |  |
| 100 | 466.9 | 175.9 | 95.14 | 18.42 |  |

It may be useful also to demonstrate the influence of the injection rate $q_{T}$ on the pressure increase at the well. All other conditions remaining the same, the pressure increase at the well bore will be directly proportional to $q_{T}$. This is shown in Figure 5, for $\mathrm{q}_{\mathrm{T}}$ ranging from about 3 to 1000 U.S. gpm, with other conditions as given in Table I.

## PRESSURE BUILD-UP vs. DISTANCE AND TIME

The increase in pressure in the disposal formation as a result of waste injection, at a distance $r$ from the well, at time $t$, is given (van Everdingen, 1968) by:

$$
\begin{equation*}
P_{t}=-1 / 2 E i\left(-r^{2} / 4 t\right) \tag{5}
\end{equation*}
$$

where $E i(x)$ is the exponential integral $\int_{x}^{\infty} e^{-v} / y d y$,
$r$ is expressed in multiples of the well radius, and
$t$ is again dimensionless time.
Corresponding values for $\Delta \mathrm{P}$ are found after multiplication by $14.696 q_{\mathrm{t}}$. Results for distances of 1000, 10,000, and $100,000 \mathrm{ft}$, for 1, 10 and 100 years after the start of injection, are given in Table III and plotted in Figure 4. Values for - Ei (- $r^{2} / 4 t$ ) for various values of $r^{2} / 4 t$ are listed in Table IV.

If the confining beds overlying the disposal formation possess a measurable permeability, the influence of leakage through the confining beds on pressure build-up in the disposal formation can be taken into account through the use of the modified exponential integral: $\operatorname{Eim}(x, y)=\int_{x}^{\infty} \frac{1}{y} \exp \left(-z-\frac{y^{2}}{4 z}\right) d z$. For this purpose the parameter $r_{1} / B$ is introduced, which takes into account the relation between permeability and thickness of both the disposal formation and the confining beds:

$$
\begin{equation*}
r_{1} / B=r_{1} / \sqrt{\left(\kappa h / k_{c} h_{c}^{-1}\right)} \tag{6}
\end{equation*}
$$

Methods of determining the confining bed (or caprock) permeability can be found in Witherspoon et al. (1967). The pressure build-up is now given by

$$
\begin{equation*}
P_{t}=-1 / 2 \operatorname{Eim}\left(-r^{2} / 4 t, r_{1} / B\right) \tag{7}
\end{equation*}
$$

Values for the modified function for a range of combinations of $r^{2} / 4 t$ and $r_{1} / B$ are presented in Table $V$ (Hantush, 1956). In addition to the $r_{1} / B$ factor, the model developed by Witherspoon and Neuman (1971) uses a $\beta$ factor which accounts for contrasts between aquifer and confining beds that result from the combined effects of permeabilities and storage coefficients.

## CUMULATIVE VOLUME INJECTABLE UNDER CONSTANT PRESSURE

To determine the cumulative volume $\mathrm{O}_{\mathrm{T}}$ that can be injected in time $T$ under a constant pressure increase $\Delta P$, the time $T$ is again converted to dimensionless units using equation 1 ; the value of the dimensionless volume $Q_{t}$ is determined using the $Q_{t}$ function, which gives the cumulative volume of fluid produced from or injected into a formation of unit thickness, if from time zero onward the pressure at the well bore was decreased (or increased) by 1 atmosphere (van Everdingen, 1968). Values for the $Q_{t}$ function are given in Table VI and plotted in Figure 6. Then using equation $3, Q_{t}$ is converted to $Q_{T}$ in $\mathrm{cm}^{3}$ and $\mathrm{m}^{3}$. The results of such a calculation, using values for the

TABLE IV. Values of exponential integral - Ei ( $-\mathrm{r}^{\mathbf{2}} / 4 \mathrm{t}$ ) for values of $\mathrm{N}=\mathbf{r}^{\mathbf{2}} / 4 \mathrm{t}$ between $1.0 \times 10^{15}$ and 9.9

Table VI. Cumulative volume $\mathbf{Q}_{\mathbf{t}}$ injected per atmosphere pressure increase into a formation of unit thickness, as a function of dimensionless time $t$.

| $t$ | $Q_{t}$ | $t$ | $Q_{t}$ |
| :--- | :--- | :--- | :--- |
| $10^{-2}$ | 0.117 | $10^{6}$ | $1.4662 \times 10^{5}$ |
| $10^{-1}$ | 0.404 | $10^{7}$ | $1.2568 \times 10^{6}$ |
| 1 | 1.568 | $10^{8}$ | $1.1021 \times 10^{7}$ |
| $10^{1}$ | 7.402 | $10^{9}$ | $0.9797 \times 10^{8}$ |
| $10^{2}$ | $4.3025 \times 10^{1}$ | $10^{10}$ | $0.8798 \times 10^{9}$ |
| $10^{3}$ | $2.9262 \times 10^{2}$ | $10^{11}$ | $0.8014 \times 10^{10}$ |
| $10^{4}$ | $2.1989 \times 10^{3}$ | $10^{12}$ | $0.7407 \times 10^{11}$ |
| $10^{5}$ | $1.7594 \times 10^{4}$ | $10^{13}$ | $0.6933 \times 10^{12}$ |

various parameters similar to those in earlier examples, are presented in Table VII. The numerical factor for conversion from $Q_{t}$ to $Q_{T}$, for $\Delta P=200 \mathrm{psi}$, is

$$
\begin{aligned}
\mathrm{Q}_{\mathrm{T}} & =\frac{200}{14.696} \times 2 \pi \times 0.15 \times 0.45 \times 10^{-4} \times 2000 \times 58.06 \mathrm{Q}_{\mathrm{t}} \\
& =67.02264 \mathrm{Q}_{\mathrm{t}}
\end{aligned}
$$

The last two columns in Table VII give the additional quantity injected during consecutive years (averages for years between 5 and 10, 10 and 20, 20 and 50, and 50 and 100 years). The slight irregularity in the decrease in annually-injected volumes is due to the averaging procedure in addition to the inherent inaccuracy in the determination of $Q_{t}$ from Figure 6.

## RELATIVE INFLUENCE OF $\kappa, \phi$ AND $\mu$ ON PRESSURE BUILD-UP

Values of the physical parameters involved in pressure build-up may vary over a wide range. Viscosity of the formation fluids can be about 1 centipoise (cp) ( $\mathrm{mNs} / \mathrm{m}^{2}$ ) in a shallow reservoir at low temperature and as low as 0.2 cp in a reservoir at a depth of $10,000 \mathrm{ft}(3048 \mathrm{~m})$ with a temperature of $90^{\circ} \mathrm{C}\left(203^{\circ} \mathrm{F}\right)$; densities may range from about 1.0 to about $1.25 \mathrm{~g} / \mathrm{cm}^{3}$. Formation permeability can be as high as several darcys or as low as a few millidarcys
(permeability of confining beds may range down to less than $10^{-6}$ darcy); porosity values range from a few per cent to over 30\%; formation thickness may vary between a few meters and a few hundred meters.

The relative influence of the parameters $\kappa, \phi$ and $\mu$ on the pressure increase $\Delta P$, through their influence on the dimensionless $t$ and $q_{t}$, can be demonstrated by comparison of pressure increases after 1 day ( $86,400 \mathrm{~s}$ ) of fluid injection at a rate of $6000 \mathrm{~cm}^{3} / \mathrm{s}(95.1$ U.S. gpm) into a disposal formation with a thickness $h=2000 \mathrm{~cm}$ ( 65.57 ft) (Table VIII). The ranges for the three parameters are as indicated in Table I. Dimensionless time $t$ increases with increasing permeability $\boldsymbol{k}$, and with decreasing porosity $\phi$ and fluid viscosity $\mu$. Dimensionless injection rate $q_{t}$ decreases with increasing permeability $\kappa$ and with decreasing viscosity $\mu$.

In the last two lines of Table VIII the maximum and minimum values for $t$ and $q_{t}$ are given; these are obtained by using the extreme values for $\kappa, \phi$ and $\mu$ listed in Table I. First of all it should be noted, that the minimum value for $q_{t}$ corresponds to the maximum value for $t$, and vice versa. Secondly, the large range in values of $t$ (12.758 $T$ to 38,275 T, or a factor of 3000) has a much smaller influence on the pressure increase $\Delta P$ than the smaller range in values of $q_{t}$ ( 0.09549 to 47,746 , or a factor of 500 ). This is because the logarithm of $t$ is used in equation 4 to calculate $P_{t}$ (pressure increase per unit rate of injection and unit thickness), which is then multiplied by $q_{t}$ to obtain $\Delta P$.

Finally, it should be pointed out that the extremes for $t, q_{t}$ and $\Delta P$ calculated here are somewhat unrealistic, because in practice the porosity $\phi$ and permeability $\kappa$ often increase or decrease together. The variation in $t$ and $q_{t}$ is therefore largely a function of the potential variation in $\kappa$.

## HYDRAULIC FRACTURING AND SAFE INJECTION PRESSURE

When a constant injection rate is maintained in an injection well, the fluid pressure in the formation increases

Table VII. Cumulative volume $Q_{T}$ injected under pressure $\Delta P=200$ psi, after various times $T . \kappa=0.1$ darcy; $\phi=15 \% ; \mu=0.5 \mathrm{cp} ; \mathrm{h}=2000 \mathrm{~cm} ;$ $r_{w}=3$ in ( 7.62 cm ).

| Time years | t | $Q_{t}$ | $\mathrm{Q}_{\mathrm{T}}, \mathrm{cm}^{3}$ | $\mathrm{Q}_{\mathrm{T}}, \mathrm{m}^{\mathbf{3}}$ | Injection, $\mathrm{m}^{3 / y e a r}$ | Injection USgal/year |

with time. Ultimately, it may reach a critical value at which "hydraulic fracturing" of the formation takes place.

Fractures induced by fluid pressure in an injection well tend to follow planes parallel to the largest and intermediate principal compressive stresses in the subsurface, and perpendicular to the direction of the least principal stress. The orientation of hydraulically-induced fractures is thus strongly influenced by the prevailing state of stress in the surrounding rocks (Hubbert, 1971).

At shallow depth in regions under lateral compression the least principal stress is nearly vertical, which leads to horizontal orientation of hydraulically-induced fractưres. At greater depths, in tectonically relaxed regions, often characterized by some normal faulting, the greatest principal stress is usually nearly vertical, the intermediate and least principal stresses nearly horizontal. The orientation of hydraulic fractures in such a region can be expected to be vertical, perpendicular to the least principal stress, and parallel to the strike of any existing normal faults in the area. The effectiveness of confining strata will undoubtedly be adversely affected by the occurrence of this type of hydraulic fracture.

Another consequence of fluid injection under high pressure may be differential movement of parts of the rock mass along joints, fractures or bedding planes that deviate somewhat from a direction perpendicular to the least principal stress. Shear stress across such a discontinüity will häve some finite value. If residual or active tectonic stresses are present in the rock, slippage and possibly minor earthquakes may result from increases in fluid pressure (Hubbert, 1971).

During injection tests in which the injection pressure is increased gradually to test the intake capacity of the disposal formation, the occurrence of hydraulic fracturing causes a sudden increase in injection rate or a sudden drop in injection pressure. This is the result of a sudden increase in the effective permeability of the formation caused by:
(1) parting of the rock along bedding planes; (2) opening of joints and fractures. However, a sudden increase in injection rate may also reflect sudden compaction of adjacent or included shale beds, or the yielding of improperly set packers in the borehole, or casing failure. If the formation is re-tested at a lower pressure after hydraulic fracturing has taken place, the original relationship of pressure vs. input rate should theoretically be re-established.

Hydraulic fracturing is used to advantage in the petroleum industry, to increase the permeability of oil-andgas producing formations; the permeability is increased permanently by adding sand or another "propping" agent to the injection fluid, to maintain the fractures in an open position. A re-test in this case should reflect the increased permeability of the formation around the well bore. Hydraulic fracturing is also used in the solution mining of evaporite beds, to create horizontal communication between brine wells.

The direction in which hydraulic fractures are initiated can be controlled by proper "notching" of the formation (Aughenbaugh and Pullen, 1970). The direction of propagation of such fractures, however, is essentially a function of the existing stress field in the rocks, and the physical characteristics of the rocks involved; it may be predictable, but it cannot really be controlled. It should further be realized that horizontal hydraulic fracturing, followed by propping (either by sand or grout, or by continued hydraulic pressure) reduces the effective horizontal compressive stresses to a certain extent, while it increases the vertical compressive stress near the borehole (McClain, 1970). This may eventually result in one of the horizontal stress axes becoming the direction of minimum compressive stress, leading to increased likelihood of future vertical fracturing.

The use of the hydraulic fracturing technique to increase the permeability of a subsurface disposal formation should therefore be discouraged until assurance can be given, that confining beds will not be damaged in the
process. It is therefore necessary to limit injection pressures to values well below the critical pressure, to prevent accidental occurrence of hydraulic fracturing.

In general it is assumed that hydraulic fracturing will occur when the fluid pressure in the formation exceeds the pressure $P_{o}$ that results from the weight of the saturated rock column overlying the formation (minus any vertical strain resulting from possible horizontal compressive stresses affecting the overburden column). The value of $\mathrm{P}_{\mathrm{o}}$ thus determines the maximum limit of the total pressure allowable in the formation during injection. This total pressure equals the sum of the injection pressure $P_{i}$, maintained at the wellhead, and the pressure $P_{w}$ of the column of waste fluid in the hole, minus the pressure loss $P_{f r}$, which results from friction between the moving fluid and the stationary wall of tubing or well casing:

$$
\begin{array}{ll} 
& P_{o}=P_{i}(\max )+P_{w}-P_{f r} \\
\text { or } \quad & P_{i}(\max )=P_{0}-P_{w}+P_{f r} \tag{9}
\end{array}
$$

In most cases it will be impossible to give more than a first approximation of the overburden pressure. Assuming an average mineral density $\rho_{\text {mo }}$, an average fluid density $\rho_{\mathrm{fo}}$, and an average porosity $\phi_{o}$ for the overburden material, the average overburden density $\rho_{0}$ can be calculated from the relation:

$$
\begin{equation*}
\rho_{\mathrm{o}}=\rho_{\mathrm{mo}}+\left(\rho_{\mathrm{fo}}-\rho_{\mathrm{mo}}\right) \phi_{\mathrm{o}} \tag{10}
\end{equation*}
$$

The pressure exerted by a unit thickness of this average overburden material is:

$$
\begin{equation*}
\delta P_{0}=\rho_{0} \times 0.434 \mathrm{psi} / \mathrm{ft} \text { or } \rho_{0} \times 1.424 \mathrm{psi} / \mathrm{m} \tag{11}
\end{equation*}
$$

and the pressure exerted by the full overburden column of thickness $Z$ is:

$$
\begin{equation*}
P_{0}=Z \times \delta P_{0}(p s i) \tag{12}
\end{equation*}
$$

Figure 7 presents in graphical form the values for both $\rho_{0}$ and $\delta \mathrm{P}_{0}$ that result from mineral densities ranging from 2.65 to 2.87 , for porosities between 0 and $35 \%$ with fluid densities ranging from 1.0 to 1.2.

During injection the weight of each foot (meter) of the column of waste fluid in the disposal well will exert a pressure given by:

$$
\begin{equation*}
\delta P_{w}=\rho_{w} \times 0.434 \mathrm{psi} / \mathrm{ft} \text { or } \rho_{w} \times 1.424 \mathrm{psi} / \mathrm{m} \tag{13}
\end{equation*}
$$

Values for $\delta P_{w}$, for $\rho_{w}$ between 0.8 and 1.5, are plotted in Figure 8. The pressure $P_{w}$ for a waste column of height $Z_{w}$ is:

$$
\begin{equation*}
P_{w}=Z_{w} \times \delta P_{w}(p s i) \tag{14}
\end{equation*}
$$

If a positive injection pressure $P_{i}$ is maintained at the wellhead during injection, then $Z_{w}=Z$ (depth to top of disposal formation) and

$$
\begin{equation*}
P_{w}=Z \times \delta P_{w}(p s i) \tag{15}
\end{equation*}
$$

Figure 9 enables the determination of the loss of pressure per foot (meter) of smooth pipe, $\delta \mathrm{P}_{\mathrm{fr}}$, for standard
diameters ranging from $11 / 2$ to 8 inches and for flow rates between 1.6 and 1600 gallons per minute. The total pressure loss for a particular combination of pipe diameter, flow rate and well depth is:

$$
\begin{equation*}
P_{f r}=Z \times \delta P_{f r} \text { (psi) } \tag{16}
\end{equation*}
$$

Substituting equations 12, 15 and 16 into equation 9 gives:

$$
\begin{equation*}
\left(P_{i}\right) \max =Z\left(\delta P_{o}-\delta P_{w}+\delta P_{f r}\right) \tag{17}
\end{equation*}
$$

At this point in the calculations it appears prudent to apply a safety factor through multiplication of $\delta \mathrm{P}_{\mathrm{o}}$ by 0.75 to obtain the hopefully safe maximum allowable well-head pressure:

$$
\begin{equation*}
\left(P_{i}\right) \text { safe }=Z\left(0.75 \delta P_{o}-\delta P_{w}+\delta P_{f r}\right) \tag{18}
\end{equation*}
$$

Combining equation 18 with equations 10,11 and 13, and using the example values from Table 1, gives:

$$
\begin{gathered}
\left(P_{i}\right) \text { safe }=3280.8 \llbracket 0.75 \times 0.434[2.68+(1.1-2.68) \times \\
0.15]-0.434 \times 1.2+0.0107 \rrbracket=935.3 \mathrm{psi}
\end{gathered}
$$

for $\mathbf{Z}$ in feet, and gradients and losses in psi/ft;

$$
\begin{gathered}
\left(P_{i}\right) \text { safe }=1000 \llbracket 0.75 \times 1.424[2.68+(1.1-2.68) \times \\
0.15]-1.424 \times 1.2+0.0351 \rrbracket=935.4 \mathrm{psi}
\end{gathered}
$$

for $\mathbf{Z}$ in meters, and gradients and losses in psi/m.
The injection-pressure monitor on waste-injection wells should preferably be equipped with an automatic shut-off valve, activated when $P_{i}$ reaches the ( $P_{i}$ ) safe value.

## WELL AND FORMATION STIMULATION

Although hydraulic fracturing is not an acceptable formation stimulation technique for a subsurface wastedisposal operation, there are other methods that can be used to improve the intake capacity of a disposal formation: injection of acid, jetting, nitro-shooting, backwashing. A stimulation method is acceptable only as long as it improves the formation permeability, without affecting that of the confining beds. The effect of stimulation will be an increase in the permeability and porosity of the formation for some distance surrounding the well bore. In the computation of the effect it is generally assumed that, within a certain radius around the well, permeability is increased enough to be considered infinite in comparison with the original permeability of the formation, while porosity is unaffected.

The pressure increase per unit rate of injection as a function of time, after stimulation, is given by $P_{t}^{1}$. To use the following method, it is necessary to determine the new effective radius of the well $r_{\text {ws }}$, from pressure observations during injection tests at constant rate, both before and after stimulation. Assuming that $r_{w s}$ equals 25 ft (or $100 r_{w}$ ). then the value of dimensionless time $t$ will decrease by a factor $\left(r_{w s} / r_{w}\right)^{2}=10,000$ (equation 1). For values of $T$ between 1 day and 5 years, Table IX gives a comparison of $P_{+}^{1}$ and $\Delta P^{1}$ with the values of $P_{t}$ and $\Delta P$ that would have

Table IX. Reduction of injection pressure by stimulation. Stimulated radius $\mathrm{r}_{\mathrm{ws}}=25 \mathrm{ft}(762.5 \mathrm{~cm}) ; \mathrm{q}_{\mathrm{T}}=6000 \mathrm{~cm} 3 / \mathrm{s} ; \kappa=0.10$ darcy; $\mu=0.5$ $\mathrm{cp} ; \phi=15 \% ; \mathrm{h}=2000 \mathrm{~cm}$.

prevailed without stimulation; the values of other parameters are the same as in earlier examples. The last column of the table indicates a constant reduction in pressure has been obtained, equal to 161.6 psi for each $6000 \mathrm{~cm}^{3} / \mathrm{s}$ injected. This result can also be obtained from equation 4:

$$
\begin{aligned}
& \begin{aligned}
P_{t} & -P_{t}^{1}=1 / 21 \mathrm{n}\left(\mathrm{t} / \mathrm{t}^{1}\right)=1 / 2 \mathrm{n} 10,000 \\
& =4.6 \mathrm{~atm}=67.6 \mathrm{psi} .
\end{aligned} \\
& \text { Thus } \Delta P-\Delta P^{1}=2.387 \times 67.6=161.5 \mathrm{psi} .
\end{aligned}
$$

## WASTE MOVEMENT

The next point of interest is the question of how far injected waste can be expected to move in the disposal formation. Warner (1965) and McLean (1968) both presented equations to calculate the radius of the cylinder of waste around an injection well. The two equations give identical results; the one given by McLean is used here, because its application is the easiest. It applies to the injection of a fluid into a homogeneous, isotropic disposal
formation; injected fluid and original formation fluid are assumed to be incompressible, non-mixing, of identical density and viscosity, and not subject to a natural hydraulic gradient. The radius of the waste cylinder in miles, after time $T$, is:

$$
\begin{equation*}
\left(r_{e}\right) \text { miles }=0.0236\left[q_{T}^{1} \mathrm{~T} / \mathrm{H} \phi\right]^{1 / 2} \tag{19}
\end{equation*}
$$

where $q_{T}^{1}$ is injection rate in thousands of gallons per day, $T$ is time in years, $H$ is formation thickness in feet and $\phi$ is porosity as a fraction. If $q_{T}$ is expressed in $\mathrm{cm}^{3} / \mathrm{s}$, and thickness $h$ in cm , then the radius in km is given by:

$$
\begin{equation*}
\left(r_{e}\right) \mathrm{km}=0.03168\left[\mathrm{q}_{\mathrm{T}} \mathrm{~T} / \mathrm{h} \phi\right]^{1 / 2} \tag{20}
\end{equation*}
$$

Table $X$ gives the radius of the waste cylinder around an injection well, both in miles and km, after various periods of injection at a rate of $6000 \mathrm{~cm}^{3} / \mathrm{s}$, into a formation 2000 cm thick, with a porosity of $15 \%$. The results are also presented in Figure 10.

If the formation is not homogeneous and isotropic, waste "plumes" will move farther in some directions
than the distances given here for the various times. If differences exist between the densities of the waste fluid and the formation fluid in a particular case, the waste may move much farther than indicated by the results of Table $X$, in either the upper or the lower portion of the disposal formation. The answers obtained by the use of equations 19 and 20 can thus be regarded as indicating minimum distances; in a number of cases the waste can be expected to move farther from the injection well in some directions.

If the bulk compressibility of the saturated formation were taken into account, waste-movement distances would become slightly smaller:

$$
\begin{equation*}
\left(r_{\mathrm{e}}\right) \mathrm{km}=0.3168\left[\mathrm{q}_{\mathrm{T}} \mathrm{~T} / \mathrm{h} \phi(1+\mathrm{C} \Delta \mathrm{P})\right]^{1 / 2} \tag{21}
\end{equation*}
$$

Use of equation 21 produces values that normally differ by less than $2 \%$ from those obtained from equation 20.

A major portion of the relevant current literature on subsurface disposal of waste treats the effects of injection only in terms of gradients imposed by the fluid injection; the presence of natural hydrodynamic (and/or osmotic or thermal) gradients is usually disregarded. In a number of cases it may be found that natural flow rates are of the same order of magnitude as those caused by continuing waste injection. Using Darcy's law, the bulk flow velocity in a subsurface formation is given by:

$$
\begin{equation*}
\overline{\mathrm{V}}=\kappa \mathrm{I} / \mu \tag{22}
\end{equation*}
$$

In a porous medium with porosity $\phi$ the average velocity of flow through interconnected pores is larger by a factor approaching $1 / \phi$ :

$$
\begin{equation*}
V=\kappa \mathbf{I} / \mu \phi \tag{23}
\end{equation*}
$$

To express the average velocity in cm /year, equation 23 is multiplied by 83.21 (the equivalent of 1 darcy in $\mathrm{cm} /$ day for pure water at $20^{\circ} \mathrm{C}$ or $68^{\circ} \mathrm{F}$ ) and by 365 :

$$
\begin{equation*}
V=30371.65 \mathrm{KI} / \mu \phi \tag{24}
\end{equation*}
$$

For $\mathrm{I}=0.01, \mu=0.5 \mathrm{cp}, \phi=15 \%$ and $\kappa=0.1$ darcy, $\mathrm{V}=$ $404.96 \mathrm{~cm} /$ year (or $13.29 \mathrm{ft} /$ year). Values for the distance $r_{n}$ traversed by the waste under these conditions in the downstream direction are listed in Table $X$ and plotted in Figure 10. It can be seen, that $r_{n}$ gains in importance as time goes by. It is assumed in this calculation, that no dispersion takes place, and that the formation is homogeneous and isotropic.

Figure 11 presents in graphical form the average flow velocities of injected waste under a natural hydrodynamic gradient in a homogeneous isotropic aquifer, for various values of the gradient $I$, the porosity $\phi$ and the permeability $\kappa$. The lower horizontal axis of this graph indicates how far downstream the waste will move in a period of 1000 years under the natural gradient; this is independent of whether injection is continued or not. It presents a fair approximation of where the waste will be after this period of time. In any particular case the calculation will require detailed knowledge of the natural gradients in the disposal forma-
tion, as well as of the permeability and porosity distribution.

Kostin (1972) has presented a similar reasoning to determine the radius of the first of three "sanitary protective zones" to be established around each wasteinjection site. Within these zones development of water supplies would be subject to varying degrees of restriction. In all areas where groundwater is a valuäble resource, however, it appears to make more sense to turn Kostin's argument around, and to prevent waste-injection operations near locations where groundwater resources are being exploited.

The radius of the first zone is calculated from (20) and (24) for time $T_{e}$, the expected lifetime of the prospective injection operation. It represents the distance that will be travelled by the waste during this time under natural and injection-induced gradients:

$$
\begin{equation*}
R_{1}=0.03168\left[q_{T} T_{s} / h \phi\right]^{1 / 2}+0.30372 \kappa I T_{e} / \mu \phi \tag{25}
\end{equation*}
$$

The distance between a prospective waste-injection operation and any existing or anticipated groundwater developments should not be less than that indicated by equation 25 .

The outer radius of the second zone represents $R_{1}$ plus the distance travelled by the waste under the natural hydrodynamic gradient between the time of termination of waste injection $T_{e}$ and the time $T_{t}$ at which the waste can be expected to häve become "harmless":

$$
\begin{gather*}
R_{2}=R_{1}+0.30372 \kappa I\left(T_{t}-T_{e}\right) / \mu \phi= \\
0.03168\left[q_{T} T_{e} / h \phi\right]^{1 / 2}+0.30372 \kappa I T_{t} / \mu \phi \tag{26}
\end{gather*}
$$

The time $T_{t}$ at which the waste has become harmless (by neutralization, adsorption, oxidation, reduction, dilution, radioactive decay, biodegradation, etc.) has to be determined experimentally in most cases. For many presentday waste components, no data are available on which to base calculations of $T_{t}$. Kostin (1972) states that $T_{t}$ is generally much larger than $\mathbf{T}_{\mathbf{a}}$. Some waste components may not lose their harmful qualities at all. Equation 26 represents the minimum distance to be maintained between a prospective waste-injection site and any groündwater developments that make use of the first aquifers overlying or underlying the disposal formation.

The outer radius of the third zone represents $\mathbf{R}_{\mathbf{2}}$ plus the distance the injected waste would travel under the influence of development of the disposal formation by pumping at the original injection rate, in a location on the outer edge of this belt, during the whole period $T_{e}+T_{t}$ :

$$
\begin{align*}
& R_{3}=R_{2}+0.03168\left[q_{T}\left(T_{e}+T_{t}\right) / h \phi\right]^{1 / 2}= \\
& 0.03168\left[\sqrt{T_{e}+T_{t}}+\sqrt{T_{e}}\right]\left[q_{T} / h \phi\right]^{1 / 2}+ \\
& 0.30372 \kappa I T_{t} / \mu \phi \tag{27}
\end{align*}
$$

Equation 27 gives the minimum distance that would have to be maintained between a prospective waste injection site and existing or anticipated groundwater
developments producing from the disposal formation itself. Using values of 20 and 50 years for $T_{e}$ and $T_{t}$, respectively, and the example values for the other parameters listed in Table I, $R_{1}=0.715 \mathrm{~km}\left(0.444\right.$ mile), $R_{2}=0.836 \mathrm{~km}$ ( 0.520 mile), and $R_{3}=2.022 \mathrm{~km}$ ( 1.256 mile). It should be stressed here that the two factors with major influence on the above answers are $\kappa$ and I; values of both may range over several orders of magnitude. In a cavernous limestone, for instance, using a value of $\kappa=5$ darcy, and the same values for other parameters as before, the above distances would increase to $R_{1}=4.68 \mathrm{~km}$ ( 2.91 mile), $R_{2}=10.76$ $\mathrm{km}\left(6.69\right.$ mile), and $R_{3}=70.03 \mathrm{~km}$ ( 43.52 mile).

In addition to movement of the waste within the disposal formation, the waste may tend to move across confining beds, if an appreciable gradient exists in that direction (either natural or imposed). Some evidence exists. for the occurrence of osmotic effects (osmotic flow, salt filteringl across shale layers under the influence of either dissolved-solids-concentration gradients or pressure gradients. It has also been found that the permeability of rocks that contain an appreciable fraction of clay minerals increases with increasing pressure gradient, with increasing salt concentration, and with decreasing clay content; and that it depends strongly on the types of clay minerals in the rock, and the type of dissolved solids in the fluid (van Everdingen, 1968). However, for the moment the movement across the confining beds will only be treated in terms of true Darcy-type flow under a normal hydraulic gradient; the permeability is assumed to be constant, and independent of the pressure, the dissolved-solids concentration and the ion type.

Figure 12 enables determination of average flow velocity $\mathrm{V}_{\mathrm{c}}$ for injected waste under a natural hydraulic gradient across a confining bed, for a range of values of the gradient I', the permeability $\kappa_{c}$ and the porosity $\phi_{c}$. The lower horizontal axis of the graph indicates the thickness $h_{c}$ of the confining bed required to "confine" the waste for a period of 1000 years. With the present state of the art, these figures can be regarded as no more than an approximation; if non-Darcy behaviour is a significant factor, the actual figures may turn out to be either larger or smaller.

It was stated in the introduction, that waste or waste-derived material would eventually appear in the natural discharge areas of a disposal formation. In the absence of adsorption and other modifying reactions, such "waste" discharge will continue, even when waste injection is discontinued, until most of the waste material has passed through the formation. Leakage of waste through confining beds under the influence of injection-pressure build up can be expected to decrease or even stop, fairly soon after injection is discontinued, and as soon as excess pressure has been dissipated. If a natural gradient through the confining beds exists, however, leakage of waste will continue, although at a reduced rate.

Pre-existing or specially installed wells in the disposal formation, the confining beds, and/or in overlying forma-
tions could be employed to monitor both pressure build-up and waste movement. The natural discharge areas should be monitored for the appearance of waste or waste-derived materials in shallow groundwater, springs and surface waters (van Everdingen and Freeze, 1971).

## CONCLUSIONS

1. The magnitude and extent of the pressure increase in a disposal formation during continuous waste injection depends on: formation permeability, porosity, compressibility and thickness, on fluid viscosity and compressibility, on the radius of the well, and on the areal extent of the formation. They may further be affected by reactions between fluids and rocks in the formation.
2. Undesirable changes in the performance of a disposal system, whether by plugging of the well or the formation, by hydraulic fracturing, or by packer, tubing or casing failure, usually give rise to relatively rapid changes in injection pressure and/or rate.
3. Wellhead injection pressure and flow rate, waste density and temperature, and the pressure in the fluid-filled annulus between injection tubing and well casing, should be measured at the wellhead and checked regularly, to ensure early dectection of problems. They should preferably be recorded continuously to enable a full post-mortem analysis of sudden failures. Pressure recording should continue for some time after use of the injection well is stopped.
4. Automatic warning signals and/or shut-off valves should be activated by the wellhead monitor when the injection pressure reaches a previously established "maximum safe" injection pressure; potential waste-density fluctuations, affecting the weight of the waste column in the well, and thus the pressure in the formation, should be taken into account in setting the triggering pressure for the monitor. A sudden decrease in the injection pressure/injection rate ratio, indicating possibly unexpected hydraulic fracturing, or tubing, packer or casing failure, should also cause the trigging of the warning signal and/or automatic shut-off.
5. The technique of hydraulic fracturing should not be used to increase the receptive capacity of a waste disposal formation, because of the inherent risk of causing damage to overlying or underlying confining beds. Other well- and formation-stimulation techniques may be used only if they do not affect the integrity of the confining beds.
6. The radius of the waste "cylinder" in the disposal formation around an injection well as calculated from equation 19 is a minimum value. As a result of irregularities normally existing in a disposal formation, as well as possible differences in density between waste and formation fluids, the waste may move much farther and faster in some portions of the formation. The use of lost-circulation zones for waste injection, for example, will lead to "unexpected", rapid waste movement, often in unpredictable directions. Such zones in relatively
shallow formations should therefore not be used, even though they facilitate relatively high injection rates at low pressure.
7. Injected waste will move through the disposal formation under the influence of existing natural gradients, even after injection has been discontinued. Although the rate of movement may be slow, the waste may cross formation boundaries and eventually it may appear in the natural discharge areas of the flow system. Monitoring of observations wells, and of surface waters in discharge areas, for the appearance of waste components or degradation products, should therefore be continued for a considerable time after disposal has been stopped. This applies particularly in the case of toxic wastes.
8. The disadvantages of selection of the deepest suitable formation at any particular site for waste disposal are largely financial: higher drilling costs, higher costs for more and larger casing, tubing, and cementing, etc., and higher cost of materials of higher pressure rating. They are, however, outweighed by the gain in safety margins: more aggregate thickness of confining beds, less chance of accidental hydraulic fracturing, decreased rate of waste movement under natural gradients, and often a larger distance to any naturäl discharge areas. In some cases, however, the paucity of subsurface data for greater depths may necessitate the drilling of a number of test holes to define subsurface conditions more adequately.
