## Foreword

This series documents the scientific basis for the evaluation of aquatic resources and ecosystems in Canada. As such, it addresses the issues of the day in the time frames required and the documents it contains are not intended as definitive statements on the subjects addressed but rather as progress reports on ongoing investigations.
Research documents are produced in the official language in which they are provided to the Secretariat.

#### Abstract

The Northern cod (Gadus morhua) stock that inhabits waters off southern Labrador and eastern Newfoundland eastward to the edge of the continental shelf in the Northwest Atlantic Fisheries Organization (NAFO) Divisions (Divs.) 2J3KL was assessed through a Regional Peer Review Process (RPR) conducted during March 21-24 and March 30-31, 2016 in St. John's, Newfoundland and Labrador (NL). This stock is currently under a three-year management cycle, and the current assessment provided catch advice for 2016-18. The assessment also identified an indicator (based on 3 year projections of DFO research vessel (RV) total [2+] biomass) that could be used to determine whether a full assessment is warranted during interim years. The current assessment was based mainly on a new state-space population dynamics model (Northern Cod Assessment Model, NCAM) that integrates much of the existing information about the productivity of the stock. Key features of the new model are that it provides annual estimates of natural mortality (M) and fishing mortality ( F ) rates along with measures of uncertainty; the model also estimates catch and requires an interval identifying a likely range of catch (upper and lower bounds). The model integrates information from DFO RV autumn trawl surveys (1983-2015), Sentinel fishery surveys (1995-2014), inshore acoustic surveys (1995-2009) fishery catch age compositions, and partial fishery landings (1983--2015), and tagging (1983-2015). The latest assessment indicated that stock abundance (ages $2+$ ) has increased from 194 million cod in 2005 to 894 million in 2015. Total biomass (ages 2+) has increased from 78 Kt in 2005 to 539 Kt in 2015. Spawning stock biomass (SSB) has increased from 25 Kt in 2005 to 300 Kt in 2015. Recruitment (age 2) improved slightly in the last decade and the average number of age 2 s from the 2011-13 year classes corresponds to about $25 \%$ of the numbers of age 2 s observed in year classes of the 1980s. Stock status is improving, increasing from $3 \%$ of $B_{\text {lim }}$ in 2005 to $34 \%$ of $B_{\text {lim }}$ in 2015 , but SSB has been well into the critical zone since the stock collapse. Three year projections (to 2018) were also undertaken to investigate the potential impact of a range of catch options from zero catch (no fishing) to a 5 -fold increase in catch, based on model estimates of total catch for 2015 ( $6,900 \mathrm{t}$ ). The results indicated a high probability of achieving a 3-year $28 \%$ SSB interim growth milestone over the full range of catch options. Projections also indicate a low risk (<4\%) that SSB will decline by 2018 to below the 2015 value, but also a low probability (5-8\%) that the stock will grow out of the critical zone and exceed $\mathrm{B}_{\text {lim }}$ in 2018. The stock is projected to grow but still be much less than $\mathrm{B}_{\text {lim }}(60-66 \%)$ and remain in the critical zone in 2018 over the full range of catch options considered, including no fishing. Consistency with the DFO decision-making framework incorporating the precautionary approach requires that removals from all sources must be kept at the lowest possible level until the stock clears the critical zone.

# Évaluation du stock de morue (Gadus morhua) dans les divisions 2J3KL de I'OPANO en 2016 

RÉSUMÉ

Un processus d'examen régional par les pairs qui s'est tenu du 21 au 24 mars et les 30 et 31 mars 2016 à St. John's, à Terre-Neuve-et-Labrador (T.-N.-L.), a évalué le stock de morue (Gadus morhua) qui vit dans les eaux au large du sud du Labrador et à l'est de Terre-Neuve, au bord du plateau continental, dans les divisions 2J3KL de l'Organisation des pêches de l'Atlantique Nord-Ouest (OPANO). Ce stock fait l'objet d'un cycle de gestion sur trois ans et l'évaluation actuelle a permis de produire l'avis sur les prises pour 2016-2018. L'évaluation a également fixé un indicateur (fondé sur les projections sur trois ans de la biomasse totale [2+] d'après le navire scientifique du MPO ) qui pourrait servir à déterminer si une évaluation complète est justifiée pendant les années intermédiaires. La présente évaluation repose essentiellement sur un nouveau modèle de dynamique des populations de type état-espace (le modèle d'évaluation de la morue) qui intègre une bonne partie des renseignements existants sur la productivité de ce stock. Les principales caractéristiques de ce nouveau modèle résident dans le fait qu'il donne des estimations annuelles des taux de mortalité naturelle (M) et de mortalité par pêche (F), ainsi que des mesures de l'incertitude; il estime aussi les prises et nécessite un intervalle définissant une fourchette probable de prises (limites supérieure et inférieure). Le modèle intègre les données tirées des relevés au chalut d'automne effectués par le navire de recherche du MPO (1983-2015), des relevés de pêche sentinelle (1995-2014), des relevés acoustiques côtiers (1995-2009), des compositions selon l'âge des prises et des débarquements partiels (1983-2015), ainsi que de l'étiquetage (1983-2015). Selon la dernière évaluation, l'abondance du stock (âges 2+) a augmenté, passant de 194 millions de morues en 2005 à 894 millions en 2015. La biomasse totale (âges 2+) a augmenté de 78 kt en 2005 à 539 kt en 2015. La biomasse du stock reproducteur (BSR) a augmenté de 25 kt en 2005 à 300 kt en 2015. Le recrutement (âge 2) s'est légèrement amélioré depuis dix ans et le nombre moyen de poissons d'âge 2 des classes d'âge de 2011 à 2013 correspond à environ $25 \%$ de celui qui était observé dans ces classes d'âge dans les années 1980. L'état du stock s'améliore, passant de $3 \%$ de Blim en 2005 à 34 \% de Blim en 2015, mais la BSR se situe largement dans la zone critique depuis que le stock s'est effondré. Des projections sur trois ans (jusqu'en 2018) ont été réalisées afin d'étudier les incidences potentielles d'un éventail d'options de prises allant d'aucune prise (pas de pêche) à une multiplication par cinq des prises, à partir des estimations du modèle des prises totales pour 2015 (6 900 t ). Les résultats ont montré une forte probabilité d'atteindre un jalon de croissance intermédiaire de $28 \%$ de la BSR sur trois ans, pour toutes les options de prises. Les projections indiquent aussi un risque faible (<4 \%) que la BSR en 2018 chute en dessous de la valeur de 2015, mais également une faible probabilité (5 à 8 \%) que le stock sorte de la zone critique et dépasse la valeur Blim en 2018. On prévoit que le stock va croître, mais demeurer bien inférieur à la valeur Blim (60 à $66 \%$ ) et qu'il restera dans la zone critique en 2018 pour tout l'éventail des options de prises envisagées, y compris aucune pêche. Pour être conforme au cadre décisionnel de Pêches et Océans Canada (MPO), qui incorpore l'approche de précaution, il faut que les prélèvements de toutes les sources soient maintenus au plus faible niveau possible jusqu'à ce que le stock quitte la zone critique.

## INTRODUCTION

This document gives an account of the 2016 assessment of the Northern cod (Gadus morhua) stock that inhabits waters off southern Labrador and eastern Newfoundland eastward to the edge of the continental shelf in Northwest Atlantic Fisheries Organization (NAFO) Divisions (Divs.) 2J3KL (Figs. 1a-1c). The current evaluation was conducted through a Regional Peer Review Process (RPR) conducted during March 21-24 and March 30-31, 2016 in St. John's, Newfoundland and Labrador (NL). A Science Advisory Report (SAR) for the 2J3KL stock from this meeting has been produced (DFO 2016a). Details of previous assessments and stock updates for Northern cod to 2010 are reported elsewhere (Bishop et al. 1993, 1994, 1995; Bishop and Shelton 1997; Shelton et al. 1996; Lilly et al. 1998; 1999, 2000, 2001, 2003, 2004, 2005; 2006; Brattey et al. 2008a, 2009, 2011).

During 2011-16 there have been three assessments of Northern cod (2011, 2013 and 2016) with stock updates in the three intervening years (2012, 2014, 2015). The assessments in 2011 and 2013 were based on an age-based and survey-only stock assessment model (SURBA) that provides absolute estimates of total mortality rates (Z's) and relative estimates of stock size (Cadigan 2010; DFO 2011a, 2013). Modifications to the original survey-based model (SURBA +) were introduced for the 2013 assessment (Cadigan 2013). For stock updates, information on relative trends in the main stock indices (DFO RV survey, and sentinel survey) and tagging were examined (DFO 2012, 2014, 2015). During 2011-15 the stock showed some improvement, but remained well below the Limit Reference Point (LRP) (Blim) established in 2010 (DFO 2011b) and in the lower half of the critical zone.
For the current (2016) assessment a new integrated state-space population dynamics model developed specifically for Northern cod (NCAM) was introduced that utilizes much of the existing information about the productivity of the stock. The original version of NCAM (Cadigan 2015) was modified based on recommendations of a Framework Review (DFO 2016b; Cadigan 2016a). Further modifications to the model and details of data inputs for the current assessment are described below (see Results section). In addition to the NCAM model results, several other sources of information were reviewed at the assessment (e. g. physical and biological oceanography, ecosystem information, predators, prey, acoustic survey of the offshore, inshore pre-recruit surveys, industry surveys, log-books, etc.). Further details on these additional sources of information may be found in the associated Proceedings Document from this assessment (DFO 2018).

## REPORTED LANDINGS OF COD

Reported landings from this stock from the 1950's until 2009 are described in detail in previous documents (Lilly et al. 2006; Brattey et al. 2009, 2011). Reported landings for 2010-15 are added to the time-series herein (Table 3, Figs. 2, 3). Fixed gear landings (from 1975) are also updated to 2015 (Table 4, Fig. 4) and show that most of the catch throughout 2006-15 was taken by gillnets.

## REPORTED LANDINGS DURING 2010-15

## Commercial Fisheries

The "stewardship" fishery, which re-opened in 2006, has continued in the inshore during 2010-15. Note that the management year extends from April 1to March 31 the following year (since 2000), but catch statistics are reported in calendar years herein as there have been no significant landings from this stock during January-March. There was no formal Total Allowable

Catch (TAC); commercial fishers were permitted a fixed annual allowance per license holder. The allowance has varied between $2,500 \mathrm{lb}$ and $5,000 \mathrm{lb}(3,000 \mathrm{lb}$ in 2006/07, 2,500 lb in 2007/08, 3,250 lb in 2008/09, 3,750 lb in 2009/10 to 2012/13, and 5,000 lb in 2013/14 to 2015/16). There were strict limits on seasons (approximately three weeks with dates varying by region), amounts of gear (six gill nets or 3,000 hooks of long-line) and areas (typically harvesters were restricted to local areas) that could be fished and further details are available in annual Conservation Harvesting plans prepared by Fisheries Management. Small additional catches of cod also came from the sentinel fishery ( $<300 \mathrm{t}$ per year) and by-catch taken mostly during fisheries for winter flounder (Pseudopleuronectes americanus), lumpfish (Cyclopterus lumpus), herring (Clupea harengus, gillnet fishery), capelin (Mallotus villosus, trap fishery), and the bait-net fishery ( $<50 \mathrm{t}$ per year combined). There has been no directed fishery for cod in the offshore (i.e. $>12 \mathrm{~nm}$ from shore) since the moratorium. Some cod by-catch is taken by vessels fishing offshore for Greenland halibut (Reinhardtius hippoglossoides), but except for the period 2004-08 (see Brattey et al. 2009), amounts are small (generally < 10 t per annum). Similarly, small amounts of cod (generally <20 t per year) are taken as by-catch in fisheries for other species such as winter flounder, lumpfish and shrimp. By-catch of cod from the offshore of 3L has also been reported by the Scientific Council of NAFO for non-Canadian vessels fishing on the "nose" of the Grand Banks in 3L outside Canadian exclusive economic zone ( 200 nm limit)(see Table 3) but reported amounts (<300 t per year) are a small fraction of reported total landings.

Reported landings in the past six years ranged from 2,962 t in 2010 to 4,870 t in 2014 (Table 3) with most of the landings coming from the inshore (Table 5). The reported landings in 2015 were $4,436 \mathrm{t}$. During this period the inshore commercial ("stewardship") fishery accounted for most ( $>90 \%$ ) of the reported landings (Fig. 5). The Sentinel fishery has accounted for less than 300 t per year, with by-catch in all other inshore fisheries typically $<100 \mathrm{t}$ per year.
The number of ground-fish licenses in NAFO Divs. 2J3KL has diminished by 23\% during 2006-15 from over 2,500 in 2006 to approximately 2,000 in 2015 (Fig. 6). The distribution of licenses by NAFO division shows approximately $6 \%$ in $2 \mathrm{~J}, 42 \%$ in 3 K and $52 \%$ in 3 L .The number of active licenses has ranged from 2,100 to 1,700 with the lowest value in 2015 . The distribution of licenses within each NAFO Division is not uniform (Fig. 7). Although data were not available for the most recent years, the distribution has not changed and there are relatively few harvesters (i.e. $50-120$ ) in the northern unit areas ( 2 J and $3 \mathrm{Ka}-3 \mathrm{Kh}$ ) and in the extreme south (3Lj and 3 Lq ). Most of the harvesters are concentrated in 3 Ki (>600) and 3La-3Lf (300-360).
Most of the reported landings during 2010-15 were taken to the west of Notre Dame Bay around Twillingate and Fogo (unit areas $3 \mathrm{Kh} / 3 \mathrm{Ki}$ ), and in Bonavista Bay (3La) and Trinity Bay (3Lb, Table 5). There were no major changes in the distribution of landings over time as harvesters were given a fixed annual allowance and fished close to their home port; consequently, the distribution of landings largely reflects local effort, i.e. the numbers of active harvesters in each area. Most of the landings in the commercial fishery during 2015 took place in the inshore during August to early October; catches in the remaining months came mostly from the sentinel fishery and by-catch (Table 6); this is the typical monthly distribution of catches since 2006.
Monthly reported landings of cod from NAFO Divs. 2J3KL from 1983-2015 were also compiled from available catch statistics databases for Canada-Newfoundland and Labrador, CanadaMaritimes, and non-Canadian catches (Table 7). These monthly values were used in the assessment model (see below) in conjunction with tag recapture information; these values were required to estimate the fraction of harvesting that took place in any year before tagged fish were released in that year.

A detailed overview of the dockside monitoring program (DMP), which has been in place since 2005 to monitor landings, was described at the 2016 assessment meeting, but no new information on discarding, illegal fishing, or misreporting during commercial fisheries was presented. Harvesters present at the assessment meeting felt that while there could be some improvements to the DMP program and enforcement measures, the combination of these two programs resulted in a high percentage of externally monitored landings and that catches in recent years were more accurately monitored than they were prior to the implementation of the DMP. However, there remains no mechanism to estimate high-grading or discard rates in the historical catch statistics and recreational fishery landings are not directly measured (see below). There was evidence of widespread discarding of small cod during recreational fisheries in 2009 (see Brattey et al. 2011), but this issue appears to have diminished as larger cod are now more available (see below). Discarding of cod during the shrimp fishery was explored at the 2009 Northern cod Zonal Assessment Process and was estimated at <20 t per annum during 2004-08.

## Recreational Fisheries

In addition to the amounts described above, recreational fishers were permitted 5 ground-fish per person per day, and no more than 15 fish per boat, for approximately 32-35 days during summer and early autumn (July-October). Within the past decade (2006-15) there are no direct estimates of recreational landings for 2007, 2009-10, and 2013-15. Telephone surveys and estimates from fisheries officers were used to determine recreational fishery landings in 2007 and 2008, but these gave widely differing results. The reason for differences were partly related to differing estimates of effort (boat trips per day), but the reasons for the discrepancies could not be fully resolved and no estimate was used for 2007. For the 2008 recreational fishery the phone survey estimate of 818 t was subsequently revised to $1,089 \mathrm{t}$ based on better sampling of fish weights (DFO 2009) and this value was used in catch-at-age reconstruction and is shown in Fig. 5. The phone survey was discontinued after 2008. For 2011 and 2012 an estimate of recreational landings of a few hundred tons provided by fisheries officers was used in the catch-at-age reconstruction and these estimates, though uncertain, are also included in Fig. 5. Analyses of tag return information from commercial versus recreational fishers suggests that removals from recreational fisheries were substantial and much higher than was reported by fisheries officers (see Brattey et al. 2011) and averaged about 30\% of reported stewardship fishery removals during recent years (DFO 2016a). This 30\% estimate is slightly lower than was reported in previous years (DFO 2014, 2015), due to a revised method of estimating tag reporting rates which gave a higher proportion of total tags from commercial harvesters during the recent period. However, these analyses of tag returns have provided only general indications of the relatively high magnitude of recreational removals. Estimates from this method are annually quite variable (Brattey et al. 2009, 2011) and are not used in formal compilation of landings statistics.
Samples of the lengths of cod captured during the recreational fishery were taken by fisheries officers who measure cod at sea (on board recreational vessels) and at the dock in various communities; several thousand fish were measured each year (Table 8). Mean lengths tended to vary among regions and were generally highest (>60 cm) in Fogo-Twillingate (3Ki) in 2013 (Fig. 8). Overall, mean lengths tended to increase over time during 2013-2015. Sample sizes per month and site were variable (not shown) but averaged over 120 fish per month/site combination in each year. The mean lengths of cod sampled at the dock were compared with those sampled at sea for each year by month and unit area. Although not subjected to statistical analysis, 12 of 18 sites sampled in 2013 showed higher means among cod sampled at the dock than at sea, but in subsequent years this proportion diminished to 5 of 10 in both 2014 and 2015. These results suggest some discarding of smaller cod at sea by recreational fishers
during 2013, but there is no clear evidence, from comparison of these mean lengths, for extensive discarding of small fish during subsequent years.

## CATCH AT AGE

The age composition and mean length-at-age of the cod landings were initially calculated by gear, unit area and quarter as described in Gavaris and Gavaris (1983).
Sampling of cod lengths and ages (otoliths) from the various sectors of the commercial fishery has been extensive during 2010-15 (Tables 6 and 7). General sampling objectives for the fishery were to obtain a representative length frequency plus otoliths from each commercial area fished (i.e. statistical unit area such as $2 \mathrm{Jm}, 3 \mathrm{Kd}$, 3La, etc.) for each gear type and fishing period. Fishing has generally been restricted to a single short (3-4 week) period during JulySeptember, and three gear types (gillnet, hand-line and longline) account for most (>95\%) of the landings. Sampling aims to measure a minimum of 2,000 fish from each unit area, gear type, and season. A minimum sample of 200 fish per catch is measured, or the entire catch if $<200$ fish are available. In addition, the objective is to collect five otoliths per cm length group per unit area, gear type, and fishing period. Extensive additional sampling of sentinel fishery catches is conducted by sentinel fishers following a separate protocol described elsewhere (Maddock Parsons 2014).

During 2010-15 the number of cod length measurements per year has exceeded 100,000, and the numbers of otoliths has typically exceeded 5,000. All major sectors of the fishery were sampled for lengths, particularly gillnet and hand-line, and all major sectors except recreational were sampled for otoliths. Sampling was generally well spread across the inshore with most sampling taken during the main fishing period. A large percentage of the total length sampling, i.e. $\sim 80 \%$ over 2013-15, comes from the sentinel fishery where all fish are measured. For otoliths,, $40 \%$ are obtained from the sentinel fishery. Gears that contribute minor proportions of the total catches in the past six years (i.e. non-Canadian otter-trawl and shrimp trawl) were sampled intermittently.

## Historic Pattern in catch-at-age

The time-series of catch-at-age from the fishery for Northern cod (inshore and offshore combined) extends from 1962 to 2015 (Table 10). For the post-moratorium period, almost all of the catch has come from the inshore fishery which is dominated by gillnets. Descriptions of historical trends in catch at age can be found in previous assessment reports (Lilly et al. 2006; Brattey et al. 2008a, Brattey et al. 2011).

## Catch-at-age during 2010-15

In the past six years, the age range represented in samples from the commercial fishery catch extends to about age 15. Most of the catch consists of ages 5-7 (Table 8; Fig. 9) which is typical for a fishery dominated by gillnets (see Table 4). While there are no strong trends in the recent catch at age there are indications of increasing numbers of age 6 and age 7 and of the oldest age-classes (ages 10-12). In assembling the catch at age for the recent period (2010-15), there were no major discrepancies in the sum of the products (estimated catch numbers at age times weight at age) relative to reported landings; the ratio of the sum of products to reported landings was close to 1 in each year, ranging from 0.94 (2011) to 0.99 (2015).

## Catch weights-at-age

The following standard relationship was applied in deriving average weight-at-age of cod:

$$
\log (\text { weight })=3.0879 * \log (\text { length })-5.2106
$$

The mean weights-at-age calculated from mean lengths-at-age in the landings have been variable, increasing in the late 1970s and early 1980's, followed by a decline through the 1980s to low levels in the early 1990s (Table 11; Fig. 10). There has been substantial increase in the latter half of the 1990s, and weights-at-age calculated for recent years have been at or near the highest levels in the time-series. Interpretation of changes in the weights-at-age is difficult because of changes in the relative contributions of the various gear components and changes in the location and timing of catches from each gear component. For example, much of the landings prior to the moratorium came from otter trawling offshore early in the year, but since the moratorium most of the catch has come from fixed gear inshore in the second half of the year. In addition, the high proportion of landings coming from gillnets in recent years will tend to increase the calculated mean weight-at-age of those age-classes entering the selection range of the gear. This may apply in particular to ages 4 and 5 . There may also be an underestimate of weight-at-age for those age-classes leaving the selection range of gillnets. Average weights at age for the oldest ages (>age 10) tend to be more variable due to increased variability in length with age combined with small sample sizes. The overall trend in weights at age indicates values throughout the 2000s that are much higher than the low point in the early 1990s.

There are problems with the 1993 weights-at-age for ages 8 and 9 where the weights were found to be unrealistically high; these problems remain to be resolved and values for these ages have been omitted from Fig. 10.
Deviations from mean weight at age, expressed as proportions and averaged over ages 3-12, show a distinct long term trend (Fig. 11); deviations were strongly negative in the early 1970s, improved to above average during the early 1980s, but subsequently declined to negative values during the mid to late 1980s. There was a precipitous decline to strongly negative values during 1990-92 followed by a rapid increase to marginally above average during 1992-95. From the late 1990s until the present, deviations have generally been positive and weights have generally been about $20 \%$ above the long-term average (except in 2013).

## SURVEY INDICES

## DFO RESEARCH VESSEL BOTTOM-TRAWL SURVEYS OF 2J3KL

Research bottom-trawl surveys have been conducted by Canada during the autumn in Div. 2J, 3K and 3L since 1977, 1978 and 1981, respectively, and these were updated to 2015 herein. Spring surveys have been conducted by Canada in Div. 3L during the years 1971-82 and 1985-present. Spring survey results, which cover only part of the stock area (Div. 3L) have been highly variable in recent years, were not presented at the assessment.

## Survey Design

Details of the stratified random trawl survey design and changes in gear are described in previous documents (Lilly et al. 2005, 2006; Brattey et al. 2008a). Additional information on surveys conducted by DFO since the introduction of the Campelen trawl in 1995 is provided by Brodie (2005) and Brodie and Stansbury (2007). The depth-based stratification scheme and location of numbered strata is illustrated by NAFO Division in Figs. 12a-12c. Details of survey performance statistics, timing, and spatial coverage are summarized elsewhere (see Power et al. 2016 and references therein). Note that all the survey catch rate information presented
below for the 1983-94 period is in Campelen equivalents whereas values for 1995 onwards are based on actual Campelen catches.

## Autumn Surveys

Autumn Abundance and Biomass Indices: Indices of cod abundance and biomass are based on the strata-area weighted arithmetic mean catch (numbers and weights) per standard tow. In previous assessments the computations were done using a Fortran-based program (STRAP, Smith and Somerton 1981). To account for incomplete coverage of some strata in some years, estimates of biomass and abundance for non-sampled strata were previously obtained using a multiplicative model, except in 2004 (see Lilly et al. 2005). However, in the current assessment the entire time series of abundance and biomass estimates was recomputed using a new R-based version of STRAP and unfished strata are omitted from the calculations. Consequently, there may be minor differences in the estimates reported here compared with those in previous assessment reports.

There have been some changes over time in the depths covered during the survey; consequently, trends in the indices of abundance and biomass of cod has been monitored for those strata that have been fished most consistently since the start of the surveys. These "offshore index strata" are those in the depth range 100-500 m in Div. 2 J and 3 K and 55-366 m (30-200 fathoms) in Div. 3L. The inshore strata fished intermittently from 1996 onwards are not included in this index, nor are deep-water strata ( $>200$ fathoms in Div. 3L, or $>500 \mathrm{~m}$ in Div. 2 J and 3 K ). Separate estimates of abundance and biomass by stratum have been calculated for the inshore and deep-water strata (see Brattey et al. 2008a), but coverage in these areas has been poor for several years, few cod have been observed in the deep-water strata, and these are not updated here. Lilly et al. (2006) provide details on the interpretation of the autumn survey data with respect to depth and timing of the survey.
The full time series of autumn DFO research vessel survey index values by NAFO Division and total begins in 1983 and shows that the abundance and biomass indices have been low since the start of the moratorium in 1992 (Table 12; Fig. 13). The abundance index increased during 2005-09 and the biomass index increased during 2005-08; these increasing trends did not persist during 2009-2011, but have resumed during 2012-2015. In the 2015 survey, most of the abundance (87\%) and biomass (84\%) is located in the northern portion of the stock area (Divs. 2 J and 3 K ). The recent (2012-15) upward trend in the abundance index is mostly due to increased numbers of small cod (sage 4). The three-year averages (2013-15) for the abundance and biomass indices are $28 \%$ and $24 \%$, respectively, of the average during the 1980s. The 2015 survey abundance and biomass index values were 500 million fish and $448,000 \mathrm{t}$, respectively; the corresponding index values a decade ago (2005) were 61 million fish and 28,000 t .

An index of SSB was also calculated using the product of survey numbers-at-age, modelled estimates of survey mean weights-at-age (Cadigan 2016b), and cohort model estimates of proportion mature at age (see below) from the offshore autumn survey. The SSB index from the autumn DFO RV survey declined rapidly in the late 1980s and early 1990s and remained very low ( $<7,700 \mathrm{t}$, Table 12) for over a decade after the 1992 moratorium. After 2005 the SSB index shows an upward trend (Fig. 14). The three-year average SSB index increased from 23\% to $32 \%$ of the average observed in the 1980s (from 2012-14 to 2013-15). The 2015 survey SSB index values was $266,000 \mathrm{t}$; the corresponding SSB index value a decade ago (2005) was 3,000 t.

Autumn survey mean catch at age: Survey numbers at age are obtained by applying age-length keys (ALK's) to the numbers of fish at length in the samples from each Division. The current
(2015) sampling design for surveys of cod in Divs. 2J3KL requires that an attempt be made to obtain 10 otoliths per centimeter length group from two broad groupings of strata per division, roughly corresponding to eastern and western portions. This spatial stratification is intended to distribute sampling over the surveyed area. The otoliths are combined into Division specific ALK's and applied to the survey data by Division. Survey catch rates at age for the 2J3KL stock are obtained by averaging the divisional catch rates at age weighted by the area surveyed in each division.

A time series of survey catch rates at age, expressed as mean numbers per tow at age by NAFO Division and for Divs. 2J3KL combined, is given in Tables 11a-d. Mean catch per tow was generally high (mostly 50-200 fish per tow) in all three Divs. in the 1980s, but declined rapidly to generally <10 fish per tow during 1990-93. The age structure also contracted during the collapse period, with few old cod (>age 6) in the survey catches by the early-1990s. The catch rates at age remained low for more than a decade, but catch rates have been increasing since about 2005 (less so in 3L) and age structure has been expanding, with cod spawned from 2002 onwards surviving through to older ages (9-13) in recent (2012-15) surveys. Overall catch rates exceeded 50 cod per tow in both the 2014 and 2015 surveys.

The numbers of younger fish (ages 1-4) in survey catches has also improved considerably in the past 4 years, but remains well below the catch rates observed for these younger ages in the 1980s (not shown). Closer inspection of catch rates of younger ages (ages 1-4) plotted by year class indicated three general trends, depicted in Fig. 15. Year classes produced prior to 2003 show poor survival with the numbers at age 4 generally lower than at age 1 for the same year class; this is surprising given that catchability typically increases through ages 1 to 4 and may suggest that high mortality is more than offsetting the increase in catchability. In contrast, year classes produced during 2003 to 2010 show a different trend with catch rates generally increasing with age such that catch rates are generally higher by the time these cod reach age 4. This finding may suggest lower mortality rates on year classes produced during 2003-10 compared with preceding years but could also indicate changes in migratory patterns. Catch rates of the 2011 to 2013 year classes are the highest observed since the moratorium and tend to increase further with age, indicating a general improvement in recruitment and lower mortality at ages 1-4 in the most recent period.
Autumn survey catch distribution: An extensive time series of age-aggregated and disaggregated distribution plots of autumn survey catch numbers and catch weights per tow are available, but for brevity only a subset of these are shown here, to illustrate key changes in cod distribution in the recent period. A detailed history and description of changes in the distribution of cod at the time of the surveys to 2009 is given elsewhere (Shelton et al. 1996; Lilly et al. 2006; Brattey et al. 2011).
The distribution of catches from the two most recent surveys (2014 and 2015) indicate that in the most recent years cod are widely distributed in $2 \mathrm{~J}, 3 \mathrm{~K}$, and northern 3L, particularly in the waters around the edges of the banks (Fig. 16a) with several modest (10-100 cod per tow) and some larger catches (>100 per tow). The distributions depicted in Fig. 16 also show that there are consistently few or no cod in catches close to the deeper water ( $>500 \mathrm{~m}$ ) along the edge of the continental shelf or in the central and southern portion of 3L on the plateau of the Grand Banks (Figs. 16a and b). In contrast, in the mid to late 2000s, catches of only small numbers of cod per tow (<10) were widespread in $2 \mathrm{~J}, 3 \mathrm{~K}$ and northern 3L, with a few modest catches (10-100 cod per tow) restricted mostly to the 3K-3L border and the eastern side of Funk Island Bank (Brattey et al. 2011). This distribution pattern persisted through autumn surveys during 2010 and 2011 (Fig. 17a), but in subsequent surveys (2012-15) the number of sets with modest and some with large catches has increased and the distribution of larger catches has expanded
northward into northern 3K and 2J. A similar pattern is evident in the distribution of trawl catches by weight (Figs. 16a and b and 17b).

Age-disaggregated plots of catch numbers for age 1's during 2012-15 (Fig. 18a) indicate that smaller juvenile cod were widely distributed across the continental shelf in 2013 and 2014, but closer to the coast in the 2015 survey. Ages 2-4 were, in general, broadly distributed across the shelf but there were more large catches from 2013 onwards (Figs. 18b-d); older ages ( $\geq 5$, not shown) show a similar pattern to age 4's, but overall catch numbers were lower than those of younger cod.

## Growth

The lengths-at-age (Table 14) and weights-at-age (Table 15a) of cod sampled during the autumn surveys are shown in Fig. 19 and Fig. 20. Note that Table 14 gives values only for the period 2001-15; data for previous years are given in Brattey et al. 2011. There was a strong decline in length-at-age in Div. 2J and Div. 3K from the late 1970s to the early-1990s followed by an increase in length-at-age, while there was little or no decline in Division 3L over that period (Fig. 19). Mean length-at-age was mainly above average in 2011-14 in all Divisions. For most ages length was above average in 3K in 2015, although not for age 4 and age 5. Most ages had below average length in 2015 in Div. 3L.

Weight-at-age also showed a steep decline in Div. 2J and 3K during the same period that lengths were declining and as with length-at-age there was less of a trend in Div. 3L (Fig. 20). Mean weight-at-age was above average in 2011-14 in all Divisions and near average in 2015.

Annual variation in mean weight at age for Div. 2J3KL combined was examined over ages 3-7 by analyzing deviation from the average as a proportion over the time series for each age. The average mean weight-at-age from 1981 to 2015 was calculated for each age. Deviation was calculated for each age in each year by subtracting the mean for the age for the time series from the annual observation for that age and then dividing this by the mean for that age. Mean weight-at-age decreased from the beginning of the time series to the early 1990s. It increased to well above average by 1997 and has fluctuated since then but remained at near or above average (Fig. 21). Mean weight-at-age in 2012 and 2013 were among the highest in the time series but declined to near average by 2015.
The DFO RV trawl survey mean weights-at-age were also modelled using a Von Bertalanffy growth model (VonB2 model, Cadigan 2016b) to estimate beginning-of-year and mid-year weights-at-age for Northern cod during 1983-2014 and for ages 2-20. The modelled weights were required along with current assessment model output (see below) to estimate beginning-of-year SSB and for evaluating fishery biomass landings using mid-year weights. An advantage of using modelled weights is to reduce the measurement error in weight estimates. The modelled weights described in Cadigan (2016b) were updated with an additional year of survey data (weights from 2015 survey) and the modelled estimates of beginning of year weights for recent years, and projected weights, changed substantially. These results indicate that weights alone could have a considerable influence on estimates of stock biomass and SSB and in projections. Beginning-of-year model estimates for stock weights-at-age that were used in the calculation of SSB are given in Table 15b. Model estimates of mid-year catch weights-at-age used in the calculation of total catch biomass are given in Table 15c.

## Condition

Relative condition (relative K) was calculated by first fitting a length versus gutted weight regression for each division. The condition index is then observed condition divided by the condition predicted from the length weight regression for a fish of that length. Relative liver
condition (relative LK) was calculated in a similar fashion using a liver weight versus length regression. Relative K and relative LK for each year were estimated for each division using a generalized linear model with an identity link and a gamma error, with year as a class variable (Tables 16 and 17; Figs. 22 and 23). For relative K, 19 fish were found to be extreme outliers and were removed. Both Div. 2J and 3K show lower relative K in the early-1990s. There has been some increase in relative K in all Divisions since then. Relative condition remains high in Div. 2 J but is below 1 (i.e. equal to that predicted from the length-weight relationship) for Div. 3K and 3L. Relative liver condition remains high in Div. 2 J but is just below 1 (i.e. equal to that predicted from the length-weight relationship) for Div. 3K and 3L in 2015.

## Maturity

Annual estimates of age at 50\% maturity (A50) and proportions mature at age for females from the 2 J 3 KL cod stock, collected during annual autumn DFO research bottom trawl surveys, were calculated as described by Morgan and Hoenig (1997). A cohort-specific Binomial logistic regression model was used to estimate the proportion mature as a function of age and these estimated proportions (Table 18) are used in the calculation of spawning stock biomass. The estimated age at $50 \%$ maturity (A50) is used as a metric for monitoring changes in age at maturity. A50 was generally between 6.0 and 7.0 among cohorts produced in the late 1950s and around 6.0 among those produced during the late 1960's to the early 1980s, but declined thereafter (Fig. 24). Age at maturity has remained low but variable (4.9-5.7) for the 1990-2009 cohorts, with no clear trend. Estimates for the last cohort (2010) are often more uncertain because only younger ages (1-5 years) are available to estimate A50. The estimate of A50 for the 2010 cohort (5.8) is unusual and is the highest observed in the recent period; the confidence intervals for the fit to this recent cohort are not large and close inspection of the raw data indicate consistently lower observed proportions mature at each age. Estimates of A50 for the 1990 cohort onwards from the previous stock update in 2015 are overlaid on the 2016 assessment results (Fig. 23). This comparison shows that the addition of one more year of data resulted in only minor retrospective changes in A50 among 2007-09 cohorts. Males show a similar trend in A50 over time (data not shown), but tend to mature about one year earlier than females.

The number of cod older than age 6 in the offshore has increased in the past 7-8 years, but the spawning stock biomass and age composition of 2 J 3 KL cod remains somewhat contracted relative to the pre-moratorium period. A spawning stock biomass that comprises lots of older fish, or a broad age range, may result in a longer time span of spawning (Hutchings and Myers 1993; Trippel and Morgan 1994). Older, larger fish also produce more viable eggs and larvae (Solemdal et al. 1995; Kjesbu et al. 1996; Trippel 1998; Stares et al. 2007). However, Morgan et al. (2007) found that there was no consistent relationship between age-composition of the spawning stock and recruitment in three populations of cod including those in 2 J 3 KL . To date, the increase in the autumn survey SSB index (Table 12) and expanded age structure in the offshore has translated into only a slight improvement in recruitment (ages 1-4, Table 13d and Fig. 15).

## NORTHERN COD ASSESSMENT MODEL (NCAM)

For Northern cod, development of an assessment model that captures the dynamics of the stock has proven difficult. In the past five decades, various assessment models have been used to evaluate stock status (see Bishop and Shelton 1997 and references therein; Cadigan 2010, 2013). Traditional analytic models (i.e. VPA) were used until just after the moratorium (Bishop et al. 1993, 1994) and briefly for the inshore portion of the stock area during 2003-07, but these models assume that catch is measured without error and that the rate of natural mortality $(M)$ is
constant. These models typically fit the data poorly (Bishop1994; Shelton et al. 1996; Lilly et al. 1998; Shelton and Lilly 2000) particularly in the early 1990s and were discontinued. In the post-moratorium period, stock status was inferred, either directly from trends in the DFO RV survey indices, or more recently (2009-11, 2013) from a survey based model (SURBA, Cadigan 2010, 2013). Neither direct or modelled survey-only based assessments can be used to evaluate the impact of future fishing (i.e. provide catch advice); the latter provides absolute estimates of trends in total mortality rates $(Z)$ but requires assumptions about natural mortality rates (M). Irrespective of the changes in methodology to assess the stock and lack of a suitable population model, the resource has clearly been at a very low level since the moratorium and well below any reasonable LRP, the latter being formally established at a Framework Review Meeting in 2010 (DFO 2011b).

Cadigan (2015) identified three main problems that need to be addressed in the development of an assessment model for Northern cod:

1. The rate of natural mortality may not be stable and may have increased substantially around the time of the moratorium. Uncertainty about M is a major issue for other Northwest Atlantic cod stocks (Sinclair 2001; Trzcinski et el. 2006; Swain 2010, 2011; Swain and Chouinard 2008);
2. Total fishery removals are uncertain (Halliday and Pinhorn 1996; Hutchings and Myers 1995; DFO 2013), most recently with respect to recreational fishery removals which are not directly estimated (DFO 2013 and other SARs); and
3. The survey catchability parameter ( $q$ ) should be constant over time if survey trends are to be used to directly infer stock trends; however, there is evidence of distributional changes in Northern cod that indicate $q$ for the DFO RV survey changed substantially during at least portions of the post-moratorium period (Brattey et al. 2008b, Cadigan 2015, Rose et al. 2011).

The current assessment was based on a new integrated state-space population dynamics model developed specifically for Northern cod (NCAM). This new model integrates much of the existing information about the productivity of the stock (Cadigan 2015). This model addresses the three main problems described above. Key features of the new NCAM model are that rather than assuming a level of natural mortality $(M)$ it provides annual estimate of $M$ and fishing mortality ( $F$ ) along with measures of uncertainty and several sources of data are integrated (see below). The model also estimates the catch, rather than assuming that reported landings are an exact measure of catch. An interval identifying a likely range of catch (lower and upper bounds) is specified and this interval was determined during discussions with stakeholders present at the assessment meeting (see below). The new model also provides estimates of the catchability parameter $(q)$ across ages for the survey indices, including a multiplicative adjustment to $q$ for the autumn DFO RV survey to account for a shift in distribution of Northern cod during 1995-2009.

## DATA INPUTS FOR NCAM

The original NCAM assessment model and subsequent changes following recommendations of 2015 Northern Cod Framework Review (DFO 2016b) are reported elsewhere (Cadigan 2015, 2016a, DFO 2016b). For brevity only the data inputs used in the final assessment model are described herein, along with any changes in how these inputs were used relative to the original and updated versions of NCAM.
The NCAM model uses the following data sources: age-disaggregated information from the autumn DFO offshore bottom-trawl survey (ages 2-14, 1983-2015), inshore Sentinel 5½" mesh
gillnet index (ages 3-10, 1995-2014), inshore acoustic biomass estimates (1995-2009), fishery catch age-composition information (ages 2-14, 1983-2015), partial fishery landings information (1983-2015) including catch bounds and monthly landings, and tagging information (1983-2014) including reporting rates. Model process errors and observation equations are included for all data sources, and NCAM provides estimates of population parameters and variance parameters as well as modelled estimates for each of the data sources described above. Further details, including model likelihood equations for the various data sources, and likelihoods for random effects such as process errors, are also described in detail in Cadigan (2015, 2016a)

## Autumn DFO Research Vessel (RV) survey

The main source of information on trends in the status of Northern cod is the autumn DFO RV survey. This survey is based on a stratified random design, has a long time-series (1983-2015), captures a broad range of ages, and covers a large portion of the stock area. This survey is not intended to provide a direct estimate of stock size, but can provide an age-disaggregated index of stock size which can be used to scale the entire population provided the catchability coefficient $q$ can be estimated for each age class in the population. Some cod can be outside the surveyed area, such as in shallow coastal water (e.g. small juveniles), or in deep water off the shelf edge, but provided there is no trend in the proportion of the population outside the area surveyed (see below), the survey can still be used to infer stock trends.
Cadigan (2015) describes in detail how the DFO RV index was used in the original formulations of NCAM. The following model changes were made for the current assessment, following recommendations of a framework review (DFO 2016). Notably, the DFO RV index time series was extended to include the results of the latest (2015) survey and the age range was expanded to include ages $2-14$ with no plus group. The survey catchability (q) was constrained to be equal for ages 6 to 14 (Fig. A1-2) and the 2004 DFO RV index was not used because of problems with survey coverage. Other changes are outlined in Cadigan (2016a). The data for ages 2-14 of Table 13d (age-disaggregated DFO RV survey index values) were used in NCAM.

## Inshore acoustic biomass estimates and DFO RV survey catchability parameter (q).

Following the collapse of the stock in the early-1990s, there is evidence from several sources that $q$ changed for Northern cod, through a distributional shift of the remnant stock to inshore regions that are not part of the autumn DFO RV survey area. A relatively large aggregation of cod was observed in Smith Sound, Trinity Bay (3L) in the spring of 1995 (Rose et al. 2011). Subsequent surveys in winter and spring gave acoustic biomass estimates ranging from 10,000 to $26,000 \mathrm{t}$ during 1995-2007, but the biomass estimates declined rapidly during 2007-09 to less than $1,000 \mathrm{t}$. Conventional tagging experiments and acoustic telemetry of cod in Smith Sound and neighbouring areas indicated overwintering cod in Smith Sound dispersed around the coast in late spring and summer (Brattey et al. 2008b, 2011; Brattey 2013) and returned to Smith Sound in autumn. Furthermore, these studies showed that the decline in biomass during 2007-09 was not due to fishing mortality or natural mortality, but was more likely a redistribution of these cod to other areas including the offshore. The autumn DFO RV survey indicated that biomass of cod in the offshore was increasing, particularly for older cod, when the Smith Sound biomass was declining and further acoustic telemetry and conventional tagging of offshore cod released in 2008 confirmed that the seasonal shoreward migration of offshore cod was taking place, similar to the pattern observed in the pre-moratorium period. Cadigan (2015) concluded that this change in migration was highly plausible and should be included in the stock assessment model through estimation of a multiplicative q at age adjustment for the DFO RV survey during 1995-2009. The size of the Smith Sound component of the stock was estimated
using published (Rose et al. 2011) acoustic biomass estimates (see Table 19) with samples (trawl and hand-line) taken during the acoustic survey providing age composition information (see Table 20).

## Sentinel surveys

Sentinel surveys for cod in the inshore were conducted by fishing enterprises operating from many communities in Divs. 2J, 3K and 3L at various times during summer and autumn from 1995 onwards. Lilly et al. (2006) summarized sentinel data up to 2005 and the most recent detailed account of the sentinel program is provided by Maddock Parsons (2014) who extended the time series to 2012. The primary goal of these surveys was to obtain information on trends in relative density of cod on traditional inshore fishing grounds during the moratorium. The sentinel surveys were also intended to provide samples that would yield information on various aspects of the biology of cod in the inshore, including age compositions, size at age, condition, maturity and feeding.

An age-disaggregated index of standardized catch rates for cod in the inshore of 2J3KL was calculated from data gathered from sentinel fishing with gillnets ( $31 / 4^{\prime \prime}$ and $5.1 / 2 " m e s h$ ) and linetrawls (Stansbury et al. 2000). The methodology for calculating the index and full details of the sentinel fishery are described elsewhere (Maddock Parsons 2014 and references therein). For the current assessment, the time series of standardized catch rates was extended to 2014 (data for 2015 were not available at the time of the assessment). The sentinel survey catchability (q) was dome shaped increasing with age to a maximum at age 7 and age 8 and decreasing thereafter (Fig. A1-2). The standardized age-disaggregated catch rate index (fish/net, ages 3-10) from $51 / 2^{\prime \prime}$ mesh gillnets was updated and result from 1995-2014 was used as an index in NCAM (Table 21).

## Catch and Catch Bounds

A time-series of catch-at-age information is used to account for fishery removals and therefore provide key information about fishing mortality rates in many assessment models; however, in NCAM the catch data was treated somewhat differently, with separate likelihood components for the total removals (with bounds, see below) and the catch proportions at age based on sampling of commercial (and recreational) landings. Cadigan (2015) notes that sampling protocols for Northern cod are complex and have changed over time and that it is not possible to evaluate the statistical properties of the catch age-composition information. The procedure used in NCAM to model age composition information is complex and based on the continuation-ratio logit, which has been used to model length and age distributions. In this procedure a variance parameter for age proportions was estimated ( $\sigma_{\mathrm{P}}$ ), then additional ad-hoc adjustments are made (more variance for younger [age $\leq 2$ ] and older [age $\geq 8$ ] ages) to account for residual variability in these ages. The total landings from 1983-2015 in the second last column of Table 1 and catch-at-age (Table 10, ages 2-14) converted to proportions with zeros replaced (see Cadigan 2015), were used as inputs to NCAM and model predicted estimates of catch biomass generated. Model predicted total landings were derived from mid-year stock weights at age, summed over ages 2-14. Mid-year stock weights were estimated using a growth model described in Cadigan (2016b).

In many fisheries catch is not measured exactly but it is an important quantity for scaling the total estimated population size. Issues that have typically generated concern about catch accuracy for Northern cod are unreported or misreported landings (either domestic or non-Canadian), discarding due to quality concerns, and dumping / discarding based on size, particularly when sized-based price-differentials are in place. In the post-moratorium period, determination of the recreational catches have also been a concern, as recreational catches are
difficult to estimate and for Northern cod no standard procedures are in place to do so. The magnitude of these potential biases in overall catch reporting and how they change over time have not been quantified for Northern cod.
For the current assessment model, an interval was required for the likely range of catch (C) through According to Cadigan (2015) this approach is better than simply assuming an exact catch or ad-hoc adjustment of reported landings. Note that NCAM estimates catch almost freely within these bounds unless there is strong indication otherwise based on all other input data and entire model structure. A censored likelihood approach was used to ensure the estimated catch could be estimated almost freely within the specified range but could only exceed the bounds by a small amount without significant cost in the likelihood function (see Cadigan 2015).
Participants at the 2016 assessment meeting agreed that potential catch inaccuracies for Northern cod likely varied over time and decided to consider three time periods based on different fishery dynamics through the pre- and post-moratorium period, as well as different states of knowledge about potential catch inaccuracies. The three time periods were:

1. A pre-moratorium period (1983-91) when catches were high;
2. An early post-moratorium period (1992-2005) when there were small inshore commercial fisheries and recreational fisheries; and
3. A recent period (2006-15) when a directed inshore fishery took place for a few weeks during summer (stewardship fishery) and a dock-side catch monitoring program (DMP) which had been in place since the 1990s was redesigned to incorporate a tier-based approach. Period (3) also included short seasonal recreational fisheries.

There are no direct estimates of these recreational landings in the total reported catch for some years, but information from tagging suggested that recreational landings were a substantial fraction of commercial removals throughout the recent period (DFO 2016). For all three time periods the lower catch bound $\left(\mathrm{C}_{\mathrm{L}}\right)$ was considered by the meeting to be $10 \%$ above reported landings. This value was arbitrary but given the potential for discards and misreported landings, $10 \%$ seemed reasonable. The catch bounds were as follows: 1983-91 [C $\left.\mathrm{C}_{\mathrm{L}}, \mathrm{C}_{\mathrm{U}}\right]=[1.1,1.5]$ with the upper bound to account mainly for discards and non-Canadian misreporting, 1992-2005 $\left[C_{L}, C_{U}\right]=[1.1,2]$ with the higher upper bound to account for the period of no DMP and more variable catch. During 2006-15, the lower bound $\left(\mathrm{C}_{\mathrm{L}}\right)$ was again fixed at 1.1, but annual estimates of the upper bound $\left(\mathrm{C}_{\mathrm{U}}\right)$ were made through differing adjustment up from reported commercial landings. Computation of $C_{u}$ for 2006-15 was based on a simple formula:

$$
C_{U}=1.1 * 1.3 * 1.1 *(\text { Commercial/Total })
$$

The rational for the first scaling factor (1.1) was a minimum adjustment to account for discarding and misreporting, and bias in visual estimation of catch weight evident from confirmation of estimated weights on Dockside Monitoring Program authorization numbers. The second factor (1.3) was an adjustment to account for recreational fisher landings, where analysis of tag returns indicated that recreational landings were on average about $30 \%$ of reported commercial landings. A third upward adjustment of 1.1 was included to account for other issues such as tagging estimates being based on numbers rather than weight and a general consideration that it was better to have the interval too wide rather than unreasonably narrow. The final ratio term (commercial/total) ensured that scaling factors were applied appropriately depending on whether estimates of recreational landings were already included in the total reported catch (i.e. 2007, 2009-10, and 2011-13). Thus, for years with no recreational landings estimate in the total reported catch, $\mathrm{C}_{\mathrm{u}}=$ total reported catch $\times 1.573$, but if estimated recreational catch was already included the adjustment is proportionally less. Note that the catch bounds used in the assessment were slightly different from those used in earlier formulations of NCAM (Cadigan

2015, 2016a) where the upper bound was double reported catch (Table 1). Table 1 summarizes the annual estimates of reported catch from various sectors of the fishery and the values of $C_{L}$ and computed values of $C_{u}$ using the formula above.

Table 1. Annual estimates of reported catch and their associated lower catch bounds $\left(C_{L}\right)$ and upper catch bounds $\left(C_{U}\right)$ from 2006-2015.

| Year | Commercial <br> Offshore <br> Catch (t) | Commercial <br> Inshore <br> Catch (t) | Recreational <br> Catch (t) | Sentinel <br> Catch (t) | Total <br> Reported <br> Catch (t) | $\mathbf{C}_{\mathbf{L}}$ | $\mathbf{C}_{\mathbf{U}}$ |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| 2006 | 22 | 2,140 | 380 | 159 | 2,701 | 1.100 | 1.352 |
| 2007 | 13 | 2,364 | - | 182 | 2,559 | 1.100 | 1.573 |

## Tagging

For Northern cod an extensive time-series of mark-recapture information is available which has the potential to provide valuable information about changes in F and M . The tagging data are in two parts. The earlier (i.e. pre-1997) tagging data are summarized in Taggart et al. (1995) and were analyzed by Myers et al. 1996, 1997. The more recent tagging data begin in 1997 and are reported in Brattey and Healey (2007) with the most recent tag return data (2007-14) provided directly by DFO.
The tagging data comprise an extensive series of tagging experiments, where batches of cod are tagged and released in a specific geographic area and time. Tagged fish are subjected to initial tagging mortality due to the stress of capture and handling in the year of release. In addition, depending on the time of year fish were released and the timing of the fishery only a fraction of $F$ and $Z$ were applied in the year of release; the fraction of fishing that occurred was estimated from a table of monthly landings (Table 7) and this is an improvement over the procedure used in previous versions of NCAM. The population of tagged cod from an experiment diminishes over time due to a combination of initial tagging mortality, tag loss, as well as fishing and natural mortality. For all experiments during 1983-2014 irrespective of capture gear type, short-term tagging survival was assumed to be $97 \%$ for tag releases in November-June, and 78\% for those during July-October (Brattey and Cadigan 2004).Tag loss was estimated using double tagging and applied using Kirkwood's model (Kirkwood 1981) with parameter estimates as described in Brattey and Healey (2007). Harvesters do not return the tags from all they fish that are captured, consequently reporting rates have to be estimated and this was achieved using a high-reward tagging scheme initiated in 1997. Tag reporting rates for Northern cod have been extensively studied (Cadigan and Brattey 2006; Konrad et al. 2016) and for the 1997 experiments onwards, annual reporting rates estimated in Konrad et al. (2016) were used as fixed constants in the original formulation of NCAM to adjust the number of tags returned annually to total numbers caught annually. However, in the current assessment formulation of NCAM reporting rates and uncertainties were estimated directly within NCAM. This was achieved by considering reporting rates in NCAM as random effects, and adding a likelihood component for these reporting rates (Cadigan 2016a). The likelihood was based on the externally derived estimates and their estimated covariance matrix.

With tag return data, estimates of tag returns in the year of release often differ substantially from the numbers observed and this can be due to a combination of non-mixing of tagged fish and local changes in $F$ which is a well-known problem in tagging analyses (Hoenig et al. 1998). The original formulation of NCAM may have over- or under-estimated M in accounting for these differences in the release year. A solution to this potential problem was to modify NCAM such that a random effect was included in the F used to estimate tag returns in the release year, to account for incomplete mixing. The $F$ in the release year for each tagging experiment was allowed to vary from the overall stock $F$ to account for possible under- or over-exploitation of tagged fish due to incomplete mixing.
Cadigan (2015) described a procedure for generating age-aggregated information from tagging so the recapture data could be used in an age-based assessment model such as NCAM.
However, the procedure limited the number of cohorts that provided useful information. In the current assessment model a different procedure was used, where the age composition of the tagged fish was estimated and then tag returns by experiment and age at capture modelled for successive years at liberty. The estimation of the age of tagged fish is described in Cadigan and Konrad (2016). The tagging data from 1997 onwards used in the assessment model comprised reported tag recaptures for years at liberty 0-9, by experiment and age-at-release for tagging conducted in 2J3KL during 1997-2014. This is substantially more tagging data than was used in the original version of NCAM (Cadigan 2015). Only experiments with >70 fish tagged in total and only experiments and ages with $\geq 10$ fish tagged were used. For the pre-1997 tagging data (i.e. 1983-96) similar selection criteria were used, except that only years at liberty 0-5 were available. In addition, there are no suitable data to estimate reporting rates for the pre-1997 tagging experiments and a composite parameter ( $\theta$ in Myers et al. 1996) combining tag reporting rates, additional initial tagging mortality, and short-term tag loss, was estimated for each experiment separately within NCAM. Overall, with respect to the tagging data, the main differences between the original version of NCAM and the formulation used in the assessment are: the use of age-disaggregated tag catch data; the amount of $F$ applied in the year of release; addition of a random effect in F to estimate tag returns in the release year; the years of tagging data used (extended to 2014); and the estimation of tag reporting rates within NCAM. Tag returns for each experiment are modelled using a simplified assessment model (Baranov catch equation) that treats tag catch-at-age the same as fishery catch at age, except that the tag catch-at-age comes from an initial population whose size is known (number of tagged cod released). Further technical details are described in Cadigan (2015, 2016a). Some addition technical changes to the final formulation of NCAM (e.g. baseline M's, F auto-correlation, and recruitment deviations) are outlined in the Proceedings (DFO 2016b). Several additional formulations and updates of the original NCAM model were also presented at the Northern cod Framework Review Meeting (Cadigan 2016a) to illustrate potential sensitivity of model results to assumptions.

## RESULTS FROM NCAM

Several sensitivity runs of NCAM were carried out and reviewed during the assessment meeting based on recommendations from the framework meeting in 2015 (DFO, 2015). These are further outlined in the proceedings document from this meeting (DFO 2016).

Results from four formulations of NCAM were presented at the Northern cod assessment (Table 22). The first formulation (labelled S1 Mshift) was based on the catch bounds used in the original formulation of NCAM, whereas for the other three runs the revised catch bounds developed during the assessment (described above) were used. The three formulations with the new catch bounds involved different treatments of M's (Table 23; baseline M's, median M's and Mshift). These three formulations gave broadly similar results for stock size and mortality rates,
but resulted in some substantial changes in NCAM estimates of total catch weight compared to the S1 Mshift run. Framework reviewers suggested that baseline M values used in NCAM should be changed to be consistent with M estimates produced by NCAM and this formulation (labelled Run 1, baseline M's) did not result in much difference in model estimates for the historic data period, but did result in substantially different projections. These changes were much less when the baseline M's were the age-specific medians of the previous estimates (labelled Run 2, median M's) and a formulation using median baseline M's was considered a better formulation. Within NCAM, M is modelled as auto-correlated random effects (over ages and years). Process error variance in M is fairly large and is an important source of variability in projections. A key issue is the large M-deviations in 1991-94 that contribute to the M process error variation. It is unclear whether M changes of similar magnitude to those of 1991-94 will occur again in the short term and a plausible way to remove this source of variation is to use higher baseline M's for 1991-94 compared with other years. This change was applied in the final formulation of NCAM (labelled Run 3, M-Shift) and resulted in slight improvement in overall model fit and a small reduction of M process error standard deviation. Thus, the M-shift formulation was used as the final assessment model formulation to assess the status of the stock and to conduct projections for harvest advice (see below).

Several NCAM fit diagnostics to the various data sources were also presented at the assessment and these demonstrated that overall the final model fit the productivity data for Northern cod well. Several of these plots, showing observed and model predicted values to each of the data sources along with various residual plots are given in Appendix A1 (Figs. A1-1 to A1-10).

## Stock size and mortality rates

Trends in stock size and mortality rate estimates from the final formulation of NCAM are illustrated in Fig. 25 and estimated values summarized in Appendix A2 (Tables A2-1 to A2-7). The abundance of Northern cod remained low for more than a decade after the collapse and moratorium in 1992, but increased in the past decade, from 194 million in 2005 to 894 million ( $95 \% \mathrm{Cl}, 636-1256$ ) in 2015 (Fig. 25; top row, left panel). Recruitment (age 2 ) in the 1990s and 2000s has been poor compared to the 1980s, but improved slightly in the last decade and the average number of age 2 s from the 2011-13 year classes corresponds to about $25 \%$ of the average numbers of age 2 s observed in year classes of the 1980's. Total biomass (ages $2+$ ) shows a similar trend to abundance and increased from 78 Kt in 2005 to $539 \mathrm{Kt}(95 \% \mathrm{CI}$, 444-654) in 2015 (Fig. 25; third row, left panel). Spawning stock biomass declined rapidly in the late-1980s and early-1990s and has remained low but shows an increasing trend in the last decade. Spawning stock biomass has increased from 25 Kt in 2005 to $300 \mathrm{Kt}(95 \% \mathrm{Cl}$, 246-362 Kt) in 2015 (Fig. 25; second row, left panel, dashed lines). Spawning stock biomass has been well into the critical zone of the Precautionary Approach Framework since the stock collapse, but has increased from 3\% of Blim in 2005 to $34 \%$ of Blim in 2015 ( $95 \% \mathrm{Cl}, 28-40 \%$ ) (Fig. 25; fourth row, left panel).
Fishing mortality $(F)$ has been highly variable during 1983-2015 (Fig. 25, first and second rows, right panels). Averages F's for ages 4-6 and 7-9 show similar trends and were higher in the 1980s and during 1998-2002, but declined abruptly when the moratorium was imposed in 1992 and again when an inshore fishery was closed in 2003. Values for $F$ on older ages (ages 7-9) were higher than those for ages 4-6, particularly just before the moratorium ( $F=0.4$ for older ages). Directed inshore fisheries for cod have continued throughout most of the postmoratorium period. Fishing mortality was low (<0.10) for both age groups during 1995-97 when inshore fishing was highly restricted, but increased rapidly reaching close to pre-moratorium values ( $F \sim=0.3$ ) for ages 7-9 when a directed inshore fishery for cod was reopened in

1998-2002. Closure of the directed inshore fishery in 2003-2005 resulted in a substantial reduction in $F$ to $<0.1$. More recently, $F$ has remained low and declined even further, to about 0.02 in 2015 in spite of increased inshore catches during the ongoing directed inshore commercial and recreational fisheries (see trends in reported landings in Fig. 5).

The rate of natural mortality $(M)$ has been variable during 1983-2015 (Fig. 25, third row, right panel), ranging from 0.3 to 0.5 in the early to mid-1980s, increasing rapidly to a peak of 2.5 during 1992-94, then declining to approximately 0.35 during 1995-99. Additional periods of high $M$ are evident in 2000-03 ( $M=0.7$ to 0.9 ) and 2009-10 ( $M=0.6$ to 0.7 ). Recent values of $M$ have been declining, from 0.70 (equivalent to an annual reduction of $50 \%$ ) in 2010 to 0.28 (equivalent to an annual reduction of 24\%) in 2015. Trends in Z (Fig. 25; bottom right panel) have been variable but follow the general pattern observed for F, with $Z$ averaging $\sim 0.6$ in the 1980s followed by a high peak of $Z \sim=2.5$ in 1991-93 and subsequent smaller peaks in 1998-2001 and 2009-10.

These results on the relative magnitudes of $F$ and $M$ around the time of the moratorium are different from published studies (e.g. Hutchings and Myers 1995; Myers et al. 1996, 1997) on the causes of the stock collapse. In the NCAM model the rate of natural mortality $(M)$ is estimated and information from tagging is integrated directly into the model, whereas in previous population dynamics models of Northern cod $M$ was an assumed constant value (typically $M=0.2$ ) and tagging data were analyzed separately. The current model can assign the sudden disappearance of cod from the DFO RV survey to either $F$ or $M$, but to be consistent with the existing tagging data the model assigns the much of the mortality to $M$. However, if there was unreported catch by Canadian and/or non-Canadian fleets and tags from these fish were not returned, then a portion of the $M$ estimated in the current analysis would actually be $F$. Investigations on the relative size of $F$ versus $M$ leading up to the moratorium are continuing.

Overall, NCAM gave estimates of $M$ that were variable over time with an extremely high peak at the time of the moratorium and these results generated considerable discussion, both at the Framework review at the assessment meeting. Various additional formulations of NCAM were run to explore this issue, including changing baseline $M$ values, and running NCAM formulations with no change in $M$ but much wider catch bounds and more catch measurement error, but none of these analyses provided support for the notion that $M$ was fairly constant. In addition, estimates of $M$ were relatively imprecise across the entire time period; in 2015, the CV on M for the final run was $31 \%$. Diagnostic runs of NCAM with various $M$ values indicated that baseline $M$ input does not significantly alter current stock size estimates, but does impact the historical estimates of stock size and stock projections.

## Projections

Projections were conducted to meet the Terms of Reference objectives for 2016 Northern cod assessment and the specified objectives were:

1. Identify the maximum level of annual removals that will enable a $50 \%$ growth in SSB over 2016-20 years with a high probability (>75\%) of success; and
2. Provide three year management advice covering the period April 1, 2016 - March 31, 2019.

Three-year projections (to 2018) were conducted to investigate the potential impact of a range of catch options from zero catch (no fishing) to a fivefold increase in catch. Issues regarding the wisdom of five year projections (to 2020) as requested in the Terms of Reference are described below. Three-year projections were based on multiplicative adjustment (again, from 0 to five-fold increase) of the model estimate of catch for 2015 ( $6,900 \mathrm{t}$ ). The age-pattern in $F$ values was assumed to be the same as in 2015. Natural mortality rates for the projection period were
calculated internally by NCAM. Because $M$ process errors are assumed to be auto-correlated across ages and years, projections of $M$ will gradually converge on the long term mean. This results in a progressive increase in $M$ during the projection period as recent values of $M$ are lower than the long-term average. Projected recruitment, stock weights (from cohort model weights), and proportions mature were assumed to be equal to the geometric mean of their 2013-15 values. Assumed recruitment (age 2) has minimal impact on the projected SSB as these fish have barely matured and contributed little to the spawning biomass by the end of the three year projection period.

The future dynamics of Northern cod are difficult to predict and when five-year projections were run CVs were extremely high and results not considered reliable for management advice. A fiveyear projection window is influenced by recruitment that has not been observed and is highly uncertain, whereas three-year projections use observed recruitment values. As a consequence of the unacceptably high uncertainty in five-year projections, the five-year growth target ( $50 \%$ SSB increase) was converted to an equivalent interim growth milestone over a three year period ( $28 \%$ SSB growth) and the probability of achieving this equivalent was evaluated for the full range of catch options considered ( 0 to 5 times current catch). The results indicated a high probability ( $\geq 85.1 \%$, see below) of achieving the $28 \%$ growth milestone over the full range of catch options.

The terms of reference for the current assessment lacked reference to the probability of exceeding the LRP for this stock, which is defined as $\mathrm{B}_{\text {lim }}$ or the average spawning stock biomass observed in the 1980s (DFO 2011b). Spawning Stock Biomass in 2015 was estimated to be $34 \%$ of $B_{\text {lim }}$ and the probability of projected SSB exceeding the $B_{\text {lim }}$ level were requested by assessment meeting participants (Table 2).

Table 2. Probability of SSB exceeding the LRP at various catch multipliers over a three year projection period.

| Projections | 0 Catch <br> Multiplier | 1 Catch <br> Multiplier | 2 Catch <br> Multiplier | 3 Catch <br> Multiplier | 4 Catch <br> Multiplier | 5 Catch <br> Multiplier |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| Probability (in \%) of <br> achieving 28\% <br> growth target by <br> 2018 | 92.9 | 91.7 | 90.3 | 88.7 | 87.0 | 85.1 |
| Risk (in \%) of SSB <br> declining below <br> 2015 value | 1.0 | 1.3 | 1.7 | 2.1 | 2.6 | 3.3 |
| Probability (in \%) of <br> exceeding B in <br> 2018 | 7.9 | 7.1 | 6.5 | 5.9 | 5.3 | 4.8 |
| SSB in 2018 as a \% <br> of B | 66.2 | 64.9 | 63.6 | 62.3 | 60.9 | 59.6 |

The projections indicate a low risk (<4\%) that SSB will decline by 2018 to below the 2015 value, but also a low probability ( $5-8 \%$ ) that the stock will grow out of the critical zone and exceed $\mathrm{B}_{\mathrm{lim}}$ in 2018. The stock is projected to grow but still be much less than $B_{\text {lim }}(60-66 \%)$ and remain in the critical zone in 2018 over the full range of catch options considered, including no fishing.

The estimated growth rate of the SSB under the three-year projections corresponds to at least $30 \%$ growth per year which is slightly higher than the maximum growth rate for Atlantic cod and therefore is unlikely to be sustained in the longer term. Short periods of high growth can occur when mortality rates are low and/or pulses of strong recruitment appear, but recruitment in Northern cod has typically been episodic and the growth rate observed in the projection results likely does not represent a sustained growth rate for the stock. High growth would also require a considerable forage biomass (i.e. capelin) to sustain the growing stock and the short-term outlook for the capelin stock is not optimistic (DFO 2016b).

## Management Advice

The estimated SSB for Northern cod has been well below the LRP since the early-1990s. Although the status of the stock is improving, the estimate of 2015 SSB is $34 \%$ of $\mathrm{B}_{\mathrm{lim}}$ and is therefore in the lower half of the critical zone. At current levels of SSB the stock is considered to have suffered serious harm and the ability to produce good recruitment is seriously impaired. When the stock is at such a low level management actions should focus on promoting increases in SSB until the stock is more resilient to the effects of fishing.

The recent increase in stock size is due to marginally stronger year-classes contributing to the SSB, a decrease in natural mortality rates and low fishing mortality rates. Projections to 2018 indicate that over a wide range of catch multipliers the SSB has a low risk ( $<4 \%$ ) of declining below the 2015 value. However, the stock also has a low probability (5-8\%) of reaching the LRP within the next three years. Consistency with the DFO decision-making framework incorporating the precautionary approach (DFO 2009) requires that removals from all sources must be kept at the lowest possible level until the stock clears the critical zone.

The peak in $M$ estimated for the period around the time of the moratorium raises the issue of whether this peak is likely to be repeated and if so how frequently. Historical information about Northern cod suggests that large scale changes in stock size have occurred in the past due to natural events rather than fishing, but these have been rare and in broad terms on a century scale rather than decadal scale or less. Nonetheless, the results of the current assessment suggest that $M$ can vary considerably over time and given that the mechanism for changes in $M$ are currently not well understood, a prudent way for fisheries managers to consider this information would be to acknowledge this variability and limit exploitation such that sufficient biomass is left to make the stock more resilient to the impact of changes in $M$.

## Indicators and procedure to trigger full assessment during interim years

The Northern cod stock is currently on a three-year management cycle and an objective of this schedule is to reduce time and resources spent on assessments that could result in no changes in scientific advice to management. A key goal of the assessment meeting was to identify stock status indicators that could be provided from interim updates conducted during periods when there is no full assessment scheduled. Stock updates are currently scheduled for March 2017 and March 2018. Previous stock updates that fell between assessment years have typically updated multi-species survey indices, sentinel indices and tagging. This requires considerable effort, particularly where thousands of otoliths have to be read and a catch-at-age or survey index SSB calculated, and this level of detail is typically not available until March when a full assessment would normally be conducted anyway.

At the assessment, several potential interim metrics of stock status or indicators of future stock performance were considered. The role of environment or prey conditions was discussed but it was unclear what thresholds could be set on environmental variables. A measured decline in capelin biomass and/or reported fisheries removals that are above modelled values were also
considered but no clear threshold could be identified at the meeting and there was concern that high natural variability in annual capelin biomass might obscure an underlying signal. There was general agreement that capelin are a key high-quality prey for cod and the cod-capelin trophic relationship could provide useful information when considered in combination with other assessment triggers. Large changes in cod stock distribution were also discussed but it was concluded that it was difficult to establish a meaningful threshold for changes in distribution.

It was generally agreed that total observed cod biomass (ages 2+) from the autumn DFO RV survey provides a reasonable metric of stock status that covers most of the stock area and is available in a reasonable timeframe that could be used as an interim year indicator. An interim indicator value would typically need to be available by early January, as this would allow sufficient time to prepare a full assessment and plan the peer review for the following March if the indicator signals that a full assessment is warranted.

Following examination of stochastic projection results from NCAM of autumn DFO RV survey total (2+) biomass for various catch multipliers (0-5x), it was agreed that a full assessment before the scheduled three-year cycle will be triggered if the autumn DFO RV survey total observed (2+) biomass is outside the $75 \%$ confidence intervals (CI) of the projected RV biomass value from NCAM for 2016 or 2017 (Fig. 25, upper panel). The $75 \% \mathrm{Cl}$ threshold was chosen over wider CIs to provide greater sensitivity to resource changes; uncertainty in projected biomass is large and substantial changes in survey biomass will not automatically trigger an assessment. Note that survey values were projected using the same settings used to project SSB.

For example, if there was no change in catch in 2016 (i.e. catch multiplier=1 or 6,900 t), the DFO RV survey biomass in autumn 2016 is projected to be $22 \%$ higher than in 2015 with $75 \%$ CI of $0.9 \%$ and $49 \%$ (Fig. 25, upper panel) If the catch in 2016 was double the 2015 value (catch multiplier=2) the projections results change slightly, and the DFO RV survey biomass in autumn 2016 is projected to be $20 \%$ higher than in 2015 with $75 \% \mathrm{Cl}$ of $-0.3 \%$ and $45 \%$ (Fig. 25, lower panel). A survey biomass outside the respective ranges for either catch multiplier would trigger a full assessment. Projected values from the current assessment can only be used to evaluate the trigger if the harvest level does not change during the interim years as each projection scenario assumes a constant catch. The NCAM estimates of actual catches can differ substantially from the reported catches and are influenced by the assumed catch bounds. In projections, catch multipliers are applied to the estimated catches from the model, not the reported landings.

${ }_{2}^{1}$ Provisional catches.
${ }^{2}$ Includes French catch and other foreign catch as estimated by Canadian surveillance.
${ }^{3}$ Figure is $4,000 \mathrm{t}$ less than Can. statistics (this quantity is 3 NO catch misreported as 3 L ).
${ }_{5}^{4}$ Derived from reported catch and Canadian surveillance estimate of foreign catch.
${ }^{5}$ Includes 5,000 t catch from the recreational fishery after the moratorium was declared.
${ }^{6}$ Canadian surveillance estimate of foreign catch.
${ }^{7}$ Includes 5,053 t estimated for the recreational fishery additional to that recorded by Canadian statistics.
${ }^{8} 1,300 \mathrm{t}$ is from the food fishery; the remainder is bycatch.
${ }^{9}$ Includes 275 t caught in the sentinel survey and 138 t caught as bycatch.
${ }^{10}$ Comprised of a sentinel survey catch of 296 t , a food fishery catch of $1,155 \mathrm{t}$ and bycatch of 422 t .
${ }^{11} 780 \mathrm{t}$ of this catch was the result of a mass mortality in Smith Sound.
${ }^{12}$ NAFO Scientific Council agreed catches.
${ }^{13}$ There was no TAC in 2006-15 but an annual allowance per licence holder for inshore vessels.
${ }^{14}$ Excludes recreational fishery.

Table 4: Fixed gear landings (t) from 1975 onwards (excludes statistical areas other than Newfoundland, $G N=$ gill net, $L L=l o n g-l i n e, H L=h a n d l i n e)$.

${ }^{1}$ Provisional catches.
${ }^{2}$ Catch is $4,000(\mathrm{t})$ less than Canadian statistics as this quantity is considered 3 NO gillnet catch misreported in 3L.
${ }^{3}$ Estimate for recreational fishery has been reported as 3 L handline.
${ }^{4}$ Comprised of sentinel survey catch of 294 t , a food fishery catch of $1,155 \mathrm{t}$ and by-catch 142 t .
${ }^{5} 780 \mathrm{t}$ of this catch was the result of a mass mortality in Smith Sound. (Actual gear used was gaff or dip net).
${ }^{6}$ Excludes recreational fishery catch.
${ }^{7}$ Cod pot.

Table 14. Average length (cm) at age of cod caught during autumn bottom-trawl surveys in Divs. 2J3KL in 2001-15. Mean lengths at age were calculated by adjusting to the length-frequency of the population. * entries are based on sample sizes <5.

Table 15a. Average weight (kg) at age of cod caught during autumn bottom-trawl surveys in Divs. 2J3KL in 2001--15. Actual weights at age were adjusted to the length-frequency of the population. * entries are based on sample sizes < 5. Values prior to 2001 are given in Brattey et al. (2011).

Table 15c. Mid-year weight-at-age estimates (kg) from a generalized Von Bertalanffy (VonB2) growth model described in Cadigan (2016b) fitted by cohort to average weight at age data for cod from autumn bottom-trawl surveys in Divs. 2J3KL from 1983-2015. Weights are projected to 2018.

Table 18. Estimated proportions mature for female cod from NAFO Div. 2J3KL from DFO RV autumn bottom trawl surveys projected forward to 2018 and back to 1958. Estimates were obtained from a cohort-specific binomial logistic regression model fitted to observed proportions mature at age. * are averages of the first or last three estimates extrapolated back or forward. ${ }^{\dagger}$ are the average of adjacent estimates for the same age group.

| Year | $\begin{gathered} \text { Age } \\ 1 \end{gathered}$ | $\begin{gathered} \text { Age } \\ 2 \end{gathered}$ | $\begin{gathered} \text { Age } \\ 3 \end{gathered}$ | $\begin{gathered} \text { Age } \\ 4 \end{gathered}$ | $\begin{gathered} \text { Age } \\ 5 \end{gathered}$ | $\begin{gathered} \text { Age } \\ 6 \end{gathered}$ | $\begin{gathered} \text { Age } \\ 7 \end{gathered}$ | $\begin{gathered} \text { Age } \\ 8 \end{gathered}$ | $\begin{gathered} \text { Age } \\ 9 \end{gathered}$ | $\begin{gathered} \text { Age } \\ 10 \end{gathered}$ | $\begin{gathered} \text { Age } \\ 11 \end{gathered}$ | $\begin{gathered} \text { Age } \\ 12 \end{gathered}$ | $\begin{gathered} \text { Age } \\ 13 \end{gathered}$ | $\begin{gathered} \text { Age } \\ 14 \end{gathered}$ |

## FIGURES

Figure 1a. Major geographic features and NAFO Division and Subdivision boundaries around NL and adjacent areas of the northwest Atlantic.

Figure 1b. Bathymetry, fishing banks, and major bays around eastern Newfoundland and Labrador. The dashed line is Canada's 200 nautical mile limit. WB=White Bay, NDB=Notre Dame Bay, BB=Bonavista Bay, TB=Trinity Bay, and CB=Conception Bay.

Figure 1c. Boundaries of commercial fishery statistical unit areas and Canada's 200 nautical mile limit (dotted line).

Figure 2. Total allowable catches (TACs) and reported landings (000's t) of cod from NAFO Divs. 2J3KL by Canadian mobile fleets (offshore), Canadian fixed gear fleets (mostly inshore), and non-Canadian fleets.

Figure 3. Reported landings (000's $t$ ) of cod in NAFO Divs. 2J3KL.

Figure 4. Reported fixed gear landings (000s $t$ ) of cod from NAFO Divs. 2J3KL by gear type. Upper panel from 1975-2015; lower panel (on expanded scale) from 1993-2015 where small scale directed inshore fisheries were permitted (within 12 nm of the coast). Note that lower panel excludes recreational fishery landings except during 2008 and 2011-12.

Figure 5. Total allowable catches (TACs) and reported inshore fixed-gear landings (000's $t$ ) of cod from NAFO Divs. 2J3KL for the fisheries during 1993-2015. Asterisks indicate years where recreational catches were taken but no estimates are available.

Figure 6. Trends in the number of groundfish licences in NAFO Divs. 2J3KL and overall number of active licences durig 2006-15.

Figure 7. Numbers of active harvesters per statistical unit area for the commercial cod fishery in NAFO Divs. 2J3KL (see Figure 1c for location of unit areas).

Figure 8. Comparison of mean lengths of cod measured at sea and at the dock by fisheries officers during the recreational fishery in NAFO Divs. 2J3KL during 2013-15.

Figure 9. Comparison of the catch numbers at age for 2J3KL cod from 2010-15.

Figure 10. Mean weight at age of 2 J 3 KL cod calculated from mean lengths at age in the commercial catch from 1972 onwards. Values for 8 and 9 yrs olds for 1993 were anomalous and are omitted.

Figure 11. Trends in deviations of mean-weight-at-age (kg) from the long-term average, calculated from mean lengths at age, for 2J3KL cod ages 3-12 in the commercial catch from 1972 onwards.

Figure 12a. Boundaries of strata used in autumn DFO research vessel bottom trawl surveys in NAFO Div. 2 J.

Figure 12b. Boundaries of strata used in autumn DFO research vessel bottom trawl surveys in NAFO Div. 3K.

Figure 12c. Boundaries of strata used in autumn DFO research vessel bottom trawl surveys in NAFO Div. 3L.

Figure 13. Trends in the offshore indices of cod abundance (upper panel) and total biomass (lower panel) from the autumn DFO research vessel bottom trawl surveys of NAFO Divs. 2J3KL. Error bars are $\pm 2$ SE's.

Figure 14. Trends in the SSB index for cod from the autumn DFO research vessel bottom trawl surveys of NAFO Divs. 2J3KL. The $y$-axis is scaled relative to the 1980s average.

Figure 15. Trends in catches rates (mean numbers per tow, MNPT) of cod ages 1-4 from the autumn DFO RV bottom trawl surveys of NAFO Divs. 2J3KL. Vertical dashed grey lines delineate three groups of year-classes with differing general trends in catch rates with age. See text for details.

Figure 16a. Age-aggregated distribution of cod catches (nos. per tow), from the autumn DFO RV survey of all strata in NAFO Divs. 2J3KL during 2014-15. Symbol size (continuous scaling) is proportional to numbers caught.

Figure 16b. Age-aggregated distribution of cod catches (weight [kg] per tow) from the autumn DFO RV survey of all strata in NAFO Divs. 2J3KL during 2014-15. Symbol size (continuous scaling) is proportional to numbers caught.

Figure 17a. Age-aggregated distribution of cod catches (nos. per tow) from the autumn DFO RV survey of index strata in NAFO Divs. 2J3KL during 2010-15. Symbol size (continuous scaling) is proportional to numbers caught.

Figure 17b. Age-aggregated distribution of cod catches (weight per tow) from the autumn DFO RV survey of index strata in NAFO Divs. 2J3KL during 2010-2015. Symbol size (continuous scaling) is proportional to catch weight (kg).

Figure 20. Mean weights at ages 2-8 of cod in NAFO Divs. 2J, 3K and 3L in 1978-2015, as determined from sampling during autumn research vessel bottom-trawl surveys. Values calculated from fewer than 5 aged fish are not plotted. There were no surveys in Div. 3L in 1978-80 and 1984.

Figure 21. Average deviation from mean weight-at-age for ages 3-7 from autumn RV bottom-trawl surveys from 1981-2015 in NAFO Divs. 2J3KL combined.

Figure 22. Relative gutted condition of cod in Divs. 3 K and $3 L$ in 1978-2015, as determined from sampling during bottom-trawl surveys in autumn. There were no surveys in Div. 3L in 1978-80 and 1984. The horizontal dashed grey line indicates a relative $K$ of 1 .

Figure 23. Relative liver condition of cod in Divs. 2J, 3K and 3L in 1978-2015, as determined from sampling during bottom-trawl surveys in autumn. There were no surveys in Division 3L in 1978-80 and 1984. The horizontal dashed grey line indicates a relative liver $K$ of 1 .

Figure 24. Age at $50 \%$ maturity ( $\pm 95 \%$ CI) by cohort for female cod in Divs. 2J3KL combined based on sampling during autumn research bottom-trawl surveys. The open circles show the results from the 2015 stock update back to the 1990 cohort. See text for details.

Figure 25. Stock size (left panels) and mortality rate estimates (right panels) $\pm 95 \%$ confidence intervals (grey lines) for 2J3KL cod during 1983-2015 from the M-shift NCAM formulation. Quantities are indicated on y-axis labels. SSB=Spawning Stock Biomass; LRP=Limit Reference Point (horizontal dashed grey line in lower left panel).

Figure 26. Upper panel: Projected changes in DFO RV 2+ biomass (solid line) $\pm 75 \%$ confidence intervals (grey dashed lines) relative to the 2015 survey biomass estimate for a constant catch multiplier of 1 (6,900 t per year). Lower panel: same as above except catch multiplier=2.

APPENDIX A1 - FIGURES OF NCAM M-SHIFT FORMULATION MODEL FITS

Figure A1-1. Retrospective estimates of recruitment, stock size, and stock size relative to $B_{\text {lim }}$ (left panels) and mortality rates (F, M, Z, right panels) from the M-shift formulation of NCAM. Circles indicate the most recent estimate for each retrospective year.

Figure A1-2. NCAM estimates of survey catchability (q), with age re-scaled to the maximum (left panels), for the DFO RV survey (upper left panel) and the sentinel gillnet catch rate index for NAFO Divs. $2 \mathrm{~J}, 3 \mathrm{~K}$ and $3 L$ (lower left panel). The maximum value of $q$ is indicated at the top of each panel. The estimated multiplicative temporal change in q for the DFO RV survey for ages 5+ during 1995-2009 is shown in the upper right panel along with an illustration of the model estimates of the proportion of the stock in Smith Sound (lower right panel).

Catch Proportion at ages 2-14

Figure. A1-3. Model predicted total catch weight relative to observed catch weight (upper left panel) and model predicted catch weight relative to assumed catch bounds (grey lines, lower panel). The left hand y-axis is in log scale. Superimposed is the observed relative to predicted catch in percent (circles) with the y-axis scale on the right hand side. Observed and predicted catch proportions-at-age are shown in the right panels.

Figure A1-4. Total observed (dots) and model predicted values (lines) for the DFO RV survey index (upper left panel) and scaled matrix plot of age-disaggregated standardized log residuals (lower left panel; black=positive, red=negative, symbols scaled by size; grey = index values of zero), Standardized residual plots by year, cohort, age, and predicted value are shown on the right panels. These residuals are the log observed survey catch minus the estimate and divided by the survey estimated standard deviation. The grey horizontal lines in the right panels indicate the average residual each year; the plotting symbols in the top right panel indicate age.

Figure A1-5. Total observed (dots) and model predicted values (lines) for the sentinel gillnet index (upper left panel) and scaled matrix plot of agedisaggregated standardized log residuals (lower left panel; black=positive, red=negative, symbols scaled by size; grey = index values of zero). Standardized residual plots by year, cohort, age, and predicted value are shown on the right panels. These residuals are the log observed survey catch minus the estimate and divided by the survey estimated standard deviation. The grey horizontal lines in the right panels indicate the average residual each year; the plotting symbols in the top right panel indicate age.

Smith Sound trawl distribution of ages 2-13

Figure. A1-6. Observed and model predicted fits ( $\pm 95 \%$ CIs) to the Smith Sound acoustic biomass estimates (left panel) and trawl sampled age compositions (right panels)

Figure A1-7. Trends in tag reporting rates estimated externally using a binomial logistic mixed effects model with temporal auto-correlation (solid black line with dashed black lines indicating $95 \%$ CIs) or internally within NCAM (solid red line). Right panels show tagging initial F deviations by experiment for tagging experiments conducted from 1997 onwards (upper panel) and prior to 1997 (lower panel).

Figure A1-8. Observed versus model predicted reported catches of tagged cod (two upper left panels) from tagging experiments prior to 1997 (left side) and from 1997 onward (right side) and conditional Poisson standardized residuals (two bottom left panels). The panels on the right show aggregate observed versus model predicted total recaptures by year. Numbers in upper right corner of right panels indicate years at liberty.

Figure A1-9. Examples of aggregate (all ages) observed versus model predicted numbers of recaptures of tagged cod by experiment and recapture year along with Poisson aggregate standardized residuals for some tagging experiments (labelled on right side y-axis) conducted prior to 1997.

Figure A1-10. Examples of aggregate (all ages) observed versus model predicted numbers of recaptures of tagged cod by experiment and recapture year along with Poisson aggregate standardized residuals for some tagging experiments (labelled on right side y-axis) conducted from 1997 onwards.

## APPENDIX A2 - TABLES OF POPULATION SIZE AND MORTALITY RATE ESTIMATES FROM THE M-SHIFT FORMULATION OF NCAM

Table A2-1. Northern cod stock size estimates with lower (L) and upper (U) 95\% confidence intervals (CI).
