## MANAGEMENT PERSPECTIVE

Toxicity and genotoxicity screening of sediments, suspended sediments, suspended particulates, soils, solid wastes and other solid phase samples have provided monitoring agencies many difficulties and challenges over the years. Initially very few solid phase bioassays were performed because of technical difficulties. After the development of microbial and enzyme based bioassays, solid phase extracts (water and solvent) were used to assess the toxicity of these solid phase samples. The use of solvent extraction on solid phase samples has often been very chemical specific and there is the question as to what degree the samples have been changed during the extraction process.

Over the years there has been a partial solution to these issus. Qualitative and semiquantitative direct solid phase toxicity testing procedures have been developed using bacterial systems and using the immunochemical detection of a cell surface reporter protein of *Escherichia coli*.

Direct solid phase toxicity testing has a major problem, the lack of standardized controls. Various researchers have used synthetic solid phase control samples prepared from silt, sand and clay for their blank controls. However, there are concerns that the makeup of the synthetic samples is physically and chemically different from that of natural sediment. Therefore we tried to address this concern by preparing two standardized natural reference sediments, a non-toxic sediment and a toxic sediment. Details on the development of these reference sediments and their responses to a direct sediment bioassay are given in this report.

# SOMMAIRE À L'INTENTION DE LA DIRECTION

Depuis des années, le dépistage de la toxicité et de la génotoxicité d'échantillons de sédiments, de sédiments en suspension, de sols, de déchets solides et d'autres types de phases solides est, pour les organismes de surveillance, une source de problèmes et de défis. À l'origine, on effectuait très peu de bio-essais en phase solide à cause de difficultés techniques. Après la mise au point de bio-essais utilisant des techniques microbiennes et enzymatiques, on a commencé à utiliser des extraits de phase solide (eau et solvant) pour évaluer la toxicité de ces échantillons de phases solides. La spécificité de l'extraction par solvant de ces échantillons était souvent restreinte à très peu d'espèces chimiques, et on pouvait également s'interroger sur le degré d'altération de l'échantillon au cours du processus d'extraction.

Au fil des ans, on a trouvé des solutions partielles à ces problèmes. On a élaboré des méthodes d'essais directs de toxicité qualitatives et semi-quantitatives, utilisant des systèmes bactériens et des techniques de détection immunochimiques d'une protéine indicatrice à la surface des cellules d'*Escherichia coli*.

Les essais directs de toxicité en phase solide sont reliés à un grave problème, le manque de témoins normalisés. Divers chercheurs ont utilisé, dans leurs essais à blanc, des échantillons témoins synthétiques en phase solide préparés à partir de limon, de sable et d'argile. Toutefois, on se préoccupe du fait que la composition de ces échantillons est distincte chimiquement et physiquement de celle d'échantillons naturels. Par conséquent, nous avons tenté d'apporter une solution à ce problème en préparant deux sédiments naturels de référence normalisés, l'un non toxique et l'autre toxique. Le rapport donne des précisions sur l'élaboration de ces sédiments de référence et sur leur tenue lors de bio-essais directs de sédiments.

## ABSTRACT

A non-toxic reference sediment was prepared from a natural environmental sample collected from a pristine area in Lake Erie, Ontario. This sediment was washed with flowing tap water and filtered through a 250 micron mesh until a negative response was obtained in the Direct Solid Phase Toxicity Testing Procedure (DSTTP). This non-toxic reference sediment sample was freeze-dried and was found to be consistently non-toxic and stable after repeated testing by the DSTTP.

A toxic (positive) reference sediment sample was prepared by spiking the non-toxic reference sediment with mercuric chloride solution. Toxicity was detected in this toxic reference sediment at the 0.039, 0.039, 0.031 and 0.031 ppm Hg<sup>++</sup> concentration levels after 0, 3, 6 and 18 weeks respectively. Details on the preparation of these reference sediments are described in this report.

# RÉSUMÉ

On a préparé un sédiment de référence non toxique à partir d'un échantillon dans son milieu naturel, prélevé dans une zone non altérée du lac Érié, en Ontario. Ce sédiment a été lavé à l'eau du robinet et passé à travers un filtre à mailles de 250 microns jusqu'à l'obtention d'une réponse négative à l'essai par la méthode directe de toxicité en phase solide (*Direct Solid Phase Testing Procedure* (DSTTP)). On a ensuite lyophilisé cet échantillon de sédiment de référence et on a constaté qu'il demeurait non toxique et stable après des essais DSTTP répétés.

On a aussi préparé un échantillon de sédiment de référence toxique (positif) en ajoutant une solution de chlorure mercurique au sédiment de référence non toxique. On a détecté la toxicité de ce sédiment de référence toxique après 0, 3, 6 et 18 semaines, avec des concentrations de  $Hg^{++}$  de 0,039, 0,039, 0,031 et 0,031, respectivement. Le rapport donne des précisions sur la préparation de ces sédiments de référence.

## **INTRODUCTION**

Toxicity and genotoxicity screening of sediments, suspended sediments, suspended particulates, soils, solid wastes and other solid phase samples have provided monitoring agencies many difficulties and challenges over the years. Initially very few solid phase bioassays were performed because of technical difficulties. These bioassays were usually carried out by using higher organisms (earthworms, benthic invertebrates such as chironomids, mayflies, amphipods and fresh water oligochaetes) and seeds or plants which are normally found in soil and sediment samples, (Day et al., 1995). As microbial and enzyme based bioassays were developed or their potentials realized, solid phase extracts (water and solvent) were used to assess the toxicity of these solid phase samples. However, in the routine toxicity screening of solid phase samples, it was often difficult to selectively detect the presence of toxicants due to their low concentration, low solubility or insolubility in the extracting solvents (Atkinson et al., 1985; Schiewe et al., 1985; Kwan,1992).

To address this conundrum, laboratories resort to a variety of extracting solvents and concentration procedures. The use of solvent extraction on solid phase samples has often been very chemical specific and there is the question as to what degree the samples have been changed during the extraction process. Also it has been noted that although sediments may contain high concentrations of toxic chemicals, toxicity or increased toxicity to organisms living in the sediments may not be observed (True and Hayward, 1990). The bioavailability of toxic compounds to benthic organisms depends on the trophic position of an organism and any toxic effect to the organism depends on its relative sensitivity to interstitial and particle bound chemicals (Swartz et al., 1986). Extraction/concentration procedures do impact on the original bioavailability of the chemicals in the sample and in doing so the potential toxicity can be estimated but the real *in situ* toxicity is rarely known. Therefore, success in detecting the true toxicity of solid phase samples is still very limited.

Over the past five or six years there has been a partial solution to the above problems. Qualitative and semi-quantitative direct solid phase toxicity testing procedures have been developed using bacterial systems (Dutka and Gorrie, 1989, Brouwer et al., 1990; Kwan, 1991) and using the immunochemical detection of a cell surface reporter protein of *Escherichia coli* ( Stubner et al., 1994).

Direct solid phase toxicity testing has one major problem, the lack of standardized controls. Tung et al. 1990 and 1991 and Day et al., 1994 have used synthetic solid phase control samples prepared from silt, sand and clay for their blank controls. However, there are concerns that the makeup of the synthetic samples are physically and chemically different from natural sediment. Therefore we have tried to address these concerns by preparing two standardized natural reference sediments, a non-toxic sediment and a toxic sediment. Details on the development of these two reference sediments and their responses to a direct sediment bioassay are given in this report.

## **METHODS AND MATERIALS**

#### Sediment Collection

Sediments were collected from Big Creek marsh, Long Point, Lake Erie, Ontario (Fig. 1) from an area designated as a Canadian Wildlife Bird Sanctury. Details of sample collection procedures are described in Reynoldson et al. (1995).

## **Sample Preparation**

In the laboratory the sediments were pooled together into a large container and mixed thoroughly. The pooled sediments were sieved through a 250 micron mesh and washed with a constant flow of tap water. Washing and sieving was continued until a negative response was obtained in the monitoring bioassay (Toxi-Chromotest). After the final washing the sediment slurry was collected in a large sterile plastic container and was allowed to settle for 48 hours. After 48 hour settling, the overlying water was discarded by siphoning.

#### **Toxicty Monitoring**

The toxicity of the sediments was checked by the Toxi-Chromotest kit following the DSTTP procedure developed by Kwan (1993) with some modifications, according to the manufacturer's instructions (Environmental Bio-detection Products Incorporation, 14 Abacus Road, Brampton, Ontario, Canada, L6T 5B7).

#### Freeze dried sediment

After the treated sediment was confirmed to be non-toxic, the sediment was divided into 500 gm portions and freeze dried using the Lyph-Lock® Stoppering Tray Dryer Freeze Dry System (Model 77560). After the freeze drying process, the original 500 gm portions were pooled into a large sterile plastic drum and rotated over a rolling machine for 48 hours to obtain a thorough mixing.

#### **Chemical analysis**

The wet untreated (natural) and the non-toxic sediments were submitted to the National Laboratory For Environmental Testing at CCIW for chemical analysis. The chemical composition of these samples is shown in Table 1.

## Positive (toxic) reference sediment

500 gm of the freeze-dried non-toxic sediment was spiked with sufficient mercuric

chloride to obtain a final concentration of 500 ppm. The sample was mixed thoroughly by hand and then tested for toxicity using the DSTTP procedure and the Toxi-Chromotest kit. Table 2 presents the data obtained from this positive (toxic) reference sediment tested at 0, 3, 6 and 18 weeks after preparation.

## **RESULTS AND DISCUSSION**

Table 1 shows the chemical composition of selected chemicals in the natural sediment collected from the Canadian Bird Century, Big Creek, Long Point, Lake Erie, Ontario, before and after washing and sieving through a 250 micron mesh.

The chemical concentrations in the treated sample were, overall, slightly lower than the untreated (natural) sample, with the exception of arsenic, sodium and tin which maintained their original concentrations. Titanium was  $0.02 \mu g/g$  higher in the untreated sample. The implication of these observations is that the majority of these chemicals are firmly bound to the sediment particles and are not water soluble. The slight difference between the washed and untreated samples may be due to the washing out of water soluble organic and inorganic complexes which were not tested for and/or the loss of chemicals adsorbed to the particles which failed to pass through the 250 micron mesh sieve.

This similarity of chemical composition was also reflected in the DSTTP test results. The natural sediment before washing was found to be slightly toxic (2+) at the 50% concentration level, the most concentrated level which can be tested by this bioassay. Nine aliquots of the washed reference sample were found to be negative in this bioassay.

Environmental sediments are unstable if kept at room or low temperatures for long periods of time due to the continuous process of biodegradation activities within the sediment. Biodegradation activities within the sediment can result in altering the chemical level(s) and/or the chemical composition in the sediment and subsequently can produce inconsistent results. To minimize the biodegradation activities in the sediment and without changing the integrity of the sample, we freeze dried our washed and sieved sediment using the Lyph-Lock® Stoppering Tray Dryer, Freeze Dry System (Model 77560).

The freeze-dried sediment was then tested for toxicity using the DSTTP procedure. Result obtained from the freeze-dried sediment indicated that the sample was slightly toxic (50% concentration). This was not surprising. This toxic effect seen in the freeze-dried non-toxic reference sample was, we believe, due to the concentration of chemicals as a result of the removal of water (approximately 75% wet weight). Thus the chemical concentrations were increased approximately three fold.

In a routine DSTTP bioassay a 50% dilution (1:2 ratio of wet sediment to reaction mixture) is usually prepared for the first concentration. However, at this dilution it was very difficult to prepare a sediment slurry due to the freeze-dried sediment absorbing too much liquid.

As a result, a 1:5 ratio (w:v) of freeze dried sediment and reaction mixture was used for the toxicity test. Results of the 1:5 dilution indicated that the freeze dried sediment was non-toxic. This non-toxic sediment, used in a 1:5 ratio was our non-toxic reference sediment.

The positive (toxic) reference sediment was evaluated for toxicity in quadruplicate using the DSTTP procedure and the Toxi-Chromotest kit immediately after preparation  $(A_{1,2,3,4})$ , three weeks after preparation  $(B_{1,2,3,4})$ , six weeks after preparation  $(C_{1,2,3,4})$  and eighteen weeks after preparation  $(D_{1,2,3,4})$ . The non-toxic freeze-dried reference sediment (1:5 ratio) was used as the negative control. Table 2 shows the results of these assays.

Toxicity was detected at the mean value of 0.039 ppm Hg<sup>++</sup> concentration levels both at 0 and three weeks and at 0.031 ppm after six and eighteen weeks of storage. This demonstrates that the freeze-dried positive (toxic) reference sediment was stable for a mininum of eighteen weeks.

## CONCLUSIONS

1. A non-toxic freeze-dried reference sediment can be prepared by collecting a natural environmental sample from a relatively pristine area and washing with running tap water and sieving through a 250 micron mesh.

2. This non-toxic freeze-dried reference sample produces reproducible negative (non-toxic) responses when tested at the ratio of 1:5 (sediment: Toxi-Chromotest reaction mixture) and produces reproducible data. A 1:5 dilution was the most suitable freeze-dried sediment concentration to use for negative control with the DSTTP and the Toxi-Chromotest kit.

3. The non-toxic reference sediment is stable at room temperature.

4. A positive (toxic) reference sediment was developed by spiking the non-toxic freeze-dried reference sediment with mercuric chloride solution. Toxicity was detected at the mean value of 0.035 ppm level.

5. The positive reference sediment was stable for a minimum of eighteen weeks.
