## I NTRODUCTION

Historical catch statistics for St. Mary's and Placentia Bays (Fig. 1) herring fisheries indicate peak average landings of about $15,000 \mathrm{~m}$ tons during the period 1945-50, principally by inshore gears in Placentia Bay. During the 1950's and early 1960's landings dropped substantially to 1000-2000 m tons but began to increase again during the late 1960's due to the expansion of the large purse-seine fleet into these areas. Landings peaked at $6,700 \mathrm{~m}$ tons in 1974 and 1975 (mainly from Placentia Bay) and have since declined to about $3,500 \mathrm{~m}$ tons since 1977.

Previously reported tagging studies (Moores and Winters 1977) have shown that a portion of St. Mary's Bay herring overwinter in Placentia Bay. A summary of more recent returns (Table 1) confirms this conclusion although it is evident that St. Mary's Bay herring also intermingle in varying degrees with the adjacent southern Avalon (Area F) and Conception Bay (Area E) areas. Since these latter two areas tend to mix more extensively with themselves rather than St. Mary's Bay (Winters and Moores 1979) the Placentia-St. Mary's Bay herring have been maintained as a unit stock for management purposes in this document.
A. 1979 Catch and age-composition data:

Landings increased slightly from 3,529 m tons in 1978 to $3,613 \mathrm{~m}$ tons in 1979 (provisional statistics) from a TAC of $3,400 \mathrm{~m}$ tons (Table 2). St. Mary's Bay continues to dominate the landings, accounting for about $60 \%$ of the total catch; prior to 1977 Placentia Bay accounted for the bulk of the catch and the reversal since then has been mainly due to the reduction in the large purse-seine fleet's allocation in Placentia Bay and the more effective catching power of the St. Mary's Bay small purse-seine (ring-net) fleet. Inshore catches have remained relatively stable between $800-900 \mathrm{~m}$ tons in recent years.

Age-composition data (Fig. 2) of commercial catches in 1979 were very similar to age-specific catches in 1978 and continues to reflect the predominance of younger fish of the 1974 year-class in Placentia Bay whereas old fish primarily of the 1968 year-class predominated in the catches in St. Mary's Bay, traditionally and pre-spawning and spawning fish operation. These data indicate that both the 1975 and 1976 year-classes are relatively weak and suggest that the 1977 year-class is probably not large.

A comparison of predicted and observed age-specific catches in 1979 (Table 3) indicates more older and less younger fish in the observed catches than predicted by Winters and Moores (1979). While this may be due to a bias in the estimation of population numbers-at-age it is more likely a reflection of the partial recruitment factors used by Winters and Moores (1978) in predicting the 1979 age-specific catch. These partial recruitment rates were calculated from the ratio of age-specific fishing mortalities from cohort analyses for the period 1972-75 when Placentia Bay, which traditionally exploits a greater representation of younger fish, dominated the total catches.

## B. Catch and effort statistics:

Since the early 1970's the participation of the large mobile fleet in the Placentia Bay winter fishery has steadily declined to the extent that since 1977 only one vessel has operated in that fishery. Catch rate statistics for this vessel ("Canada 100") are shown in Table 4 for the period 1974-78 (log records are not available for the 1979 fishery). These show a steady decline in catch-per-operating day although the 1978 catch rate is somewhat suspect since the bulk of the catch was taken outside the normal area and time of the traditional winter fishery and when the St. Mary's Bay fish would have undoubtedly emigrated to St. Mary's Bay preparatory to spawning there in mid-May. Table 5 presents a summary of catch rate data for the large purse-seine fleet as a whole and suggests that the abundance of this stock complex has been declining steadily at least up to and perhaps including 1978.

Catch rate data for the small purse-seine (ring-net) fleet which has developed in Placentia and St. Mary's Bays during the late 1970's are shown in Table 6. These are grouped into categories according to degree of experience and participation in the fishery in a manner similar to that described by Winters and Moores (1979) for East Newfoundland herring stocks. In the St. Mary's Bay fishery, for example, a large learning factor is evident from 1976-77 but this appears to be much less significant for these same boats from 1977 to 1978. Similarly comparing the 1978 and 1979 catch rates for the 3 categories of vessels indicates a substantial learning factor for new vessels in 1978 compared with those which entered the fishery in 1976. Assuming that in category (A) learning was complete by 1978 suggests a substantial decline in abundance of St. Mary's Bay herring from 1978 to 1979.

Catch rates for the ring-net fleet in Placentia Bay are highly variable and more difficult to interpret. Even those vessels with 3 years experience (Category (B)) underwent a doubling of catch rates in 1979 and, considering the age-composition data in Fig. 2, this must reflect a large increase in the catchability coefficient in 1979.

## C. Estimation of stock status:

The lack of continuity of catch rate data from either component of the mobile fleet precludes the use of conventional methodology for evaluation of current stock status. Since the 1974 year-class is very critical to prognosis of biomass and yield levels for 1980 two approaches to its estimation have been used, involving both the large and small purse-seine catch rate information.

## Method I:

The catch rate data in series (a) (Table 5) have been used to calculate the CPUE-at-age of the 1968-73 year-classes at age-groups 3 and 4 (Table 7). These have been adjusted for annual changes in partial recruitment from comparison of age-specific fishing mortalities from cohort analyses ( $F_{T}=0.40$ in 1979). The selectivity factor for the 1974 year-class at age-group 3 was obtained empirically from a comparison of purse-seine catch-at-age in Placentia Bay with the age-composition of the total catch in 1977. The CPUE of each year-class so adjusted for partial recruitment was then averaged for age-groups 3 and 4 and regressed against the mean population size of that year-class as determined from cohort analyses. Regression analyses were performed both including and excluding the 1968 year-class with the following results:
(1968 included) $Y=1.02 X-1.37\left(r^{2}=.999\right)$ Predicted $1974 Y C=32 \times 10^{+6}$
(1968 excluded) $Y=0.85 X-0.12\left(r^{2}=.995\right)$ Predicted $1974 Y C=37 \times 10^{+6}$
The two estimates of the strength of the 1974 year-class at age-group 3 were then averaged and projected ahead to 1979. Assuming that the purseseine age-composition for Placentia Bay was representative of the $5+$ population age-structure in 1979, population size-at-age for age-groups $6+$ in 1979 were determined from relative comparison with the estimated strength of the 1974 year-class at age-group 5 in 1979. An arbitrary value of 5 million recruits at age-group 2 was chosen for the 1977 year-class whereas the 1975 and 1976 year-classes were calculated from the Baranov catch equation using partial recruitment values determined from the ratio of age-specific $F$ to $F_{5}{ }^{+}$for the period 1972-77. The results of cohort analyses, initiated with the above age-specific population sizes, are shown in Table 8.

Method II:
Since the St. Mary's Bay fishery is based mainly on mature fish in the age range $6-11+$ (Fig. 2), it is assumed that the reduction in abundance of these age-groups from 1978 to 1979 is representative of their decline in the total population and that furthermore the small purse-seine CPUE in St. Mary's Bay (Table 6 - Category (A)) adequately reflects this decline from 1978 to 1979. Table 9 illustrates the results of the calculation of total mortality $(Z)$ based on these catch rates. The fishing mortality rate thereby derived ( $F=0.46$ ) was then used to calculate the $6+$ population size in 1979. This was decomposed into age-groups according to the purse-seine agecomposition for the winter fishery in Placentia Bay in 1979. The results are shown below and indicate an excellent agreement with the estimates obtained by Method I.

|  | Age-group |  |  |  |  |  |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
|  | 5 | 6 | 7 | 8 | 9 | 10 | $11+$ |  |
|  | 21450 | 690 | 4050 | 990 | 473 | 1035 | 10770 |  |

The estimates of population size obtained by Method I (Table 8) was therefore used as a basis for stock and yield prognoses for 1980.

Biomass levels (2+) increased from 35,500 tons in 1969 to 70,600 tons in 1972 (Table 8) and has declined continuously since then to slightly more than 14,000 tons in 1979. The adult biomass ( $5+$ ) increased substantially to 55,700 tons in 1973 with the recruitment of the very strong 1968 yearclass but declined to 10,000 tons in 1978 before increasing slightly to 12,400 tons in 1979, reflecting the entry of the 1974 year-class. The 1974 year-class is the strongest of the most recent year-classes, although relative to the 1968 year-class it cannot be considered to be strong. The 1975 and 1976 year-classes appear to be very weak and therefore the shortterm prognosis implies a continued decline of the adult biomass.
D. Catch prognoses:

A catch projection for 1980 at $\mathrm{F}_{0.1}=0.30$ (Moores and Winters 1977) is shown in Table 10. The partial recruitment values used reflect the historical pattern when Placentia Bay contributed the larger proportion of the total catch, and a return to this pattern is assumed for 1980. Using the ratio of total catch to catch of spring-spawners (1.14) suggests a level of removals of approximately 2,500 tons in 1980.

## E. Discussion and Conclusions:

Since 1977 St. Mary's Bay has accounted for the greater proportion of the total catch of herring from the St. Mary's-Placentia herring stock complex. This is a reversal of the recent historical pattern and is due to recent reductions in the large mobile fleet allocation, which has traditionally been taken in Placentia Bay and a concomitant increase in the small purse-seiner allocations which has mainly been taken in St. Mary's Bay. In addition, the bulk of the inshore catch is also caught in St. Mary's Bay. The analyses presented in this paper indicates a substantial fishing mortality rate on older herring (age-groups $6+$ ) which are mainly exploited in St. Mary's Bay. Furthermore, the moderately good 1974 year-class which predominates in the age-composition of catches in Placentia Bay has not shown up in significant numbers in St. Mary's Bay. It, therefore, appears that the St. Mary's Bay spawning stock has been subjected to a much greater rate of decline than the Placentia Bay adult population. An equalization of exploitation rates would, therefore, be best achieved through partitioning the TAC to include a larger proportion of the total removals from Placentia Bay.

## ACKNOWLEDGMENTS

The authors wish to thank the staff of the Pelagic Section for collecting and collating the basic data on which the above analyses were based. Mr. C.I. Barbour and Mr. R. Chaulk were responsible for age determination and tertiary development of the effort data.
