## INTRODUCTION

The southern Gulf of St. Lawrence cod stock is migratory, spending the summer in the Magdalen shallows (Div. 4T) and the winter on the edge of the Laurentian Channel off the northeast coast of Cape Breton (Subdiv. 4 Vn ). Nominal catches from this stock peaked at $110,000 \mathrm{t}$ in 1956, at a time when the herring biomass was substantially reduced by disease. Nominal catches then declined until 1967, after which they began to increase due to larger catches in Subdiv. 4 Vn (Tables 1, 2).

Catch rates began to decline in the commercial fishery in the early 1970's as did estimated population size derived from Canadian groundfish surveys. A catch quota was first introduced for this stock in 1974 by ICNAF and since then, annual quotas have been set. Reported catches dropped to a low of $22,000 \mathrm{t}$ in 1977 but have been increasing since then, coincident with the increasing biomass of this stock.

#### Abstract

A review of the Canadian fishery on the Div. 4T-4Vn (Jan.-Apr) cod stock in the 1970s was conducted as well as an analytical assessment for this stock. The Div. 4T cod fishery has been 100\% Canadian since 1977, but French catches still occur in the 4 Vn (Jan.-Apr.) fishery. Otter trawls and gillnets were the main gears used in the Div. 4T fishery, and otter trawls were virtually the only gear used in the 4 Vn (Jan.-Apr.) fishery. Virtually all of the catch of gillnets and long- and hand-lines was made by vessels under 50 gross registered tons. Most of the catch of Danish and Scottish seiners was made by vessels $50-150$ GRT. The proportion of the catch attributable to different sized otter trawlers was variable, and was dependent upon regulations in force at the time.

An analysis of samples from the commercial landings indicated that the mean length and age of cod in the Subdiv. 4Vn January to April otter trawl fishery were similar to those of the May to August Div. 4T otter trawl fishery. The mean length and age of cod caught by gillnets and long- and hand-lines were greater than those caught by otter trawls and Danish and Scottish seines. In November and December of 1979 in Div. 4T, the mean length and age of cod caught by otter trawlers over 500 GRT were similar to those of smaller trawlers.

Catch per unit efforts for most segments of the fishery indicate that the stock has been increasing in abundance since 1976. Groundfish surveys also suggest that the stock has been increasing in abundance, with the abundance estimates in 1979 being the highest since the stratified random survey design began in 1970. The research surveys also indicated that the 1975 year-class was the strongest on record. The 1977 year-class also appears to be strong, but further data are necessary for confirmation.

In 1979 the majority of the catch was comprised of the 1973 and 1974 year-classes. Although the 1975 year-class is very large, it was poorly represented in the catch, and thus in the analytical assessment, the partial recruitments of age 3 and 4 cod were substantially lower than the historical average.

Variability in growth rates was investigated for this stock, with the result that growth rate appears to be inversely related with stock biomass. This result has implications for projections based upon the assumption of constant weights-at-age. Changes in weights-at-age will have to be carefully investigated for next year's assessment.

## NOMINAL CATCHES

The trends since 1965 of Canadian and foreign catches from this stock are illustrated in Tables 1 and 2 and Fig. 1. The Canadian share of the catch has been increasing in the late 1970's as compared with the early 1970's. Tables 3, 4 and 5 indicate the nominal catch of cod by several gears in 4TVn (Jan-Apr) cod during the last three years. Table 6 indicates the breakdown of the catch by gear for 1971 to 1979. Otter trawls and gillnets were the two major gears, with Danish and Scottish seiners accounting for an increasing portion of the Div. 4T catch. The nominal catch for each gear type in Table 6 is broken down by vessel size in Table 7, and the relative proportion of the Canadian catch caught by different sized otter trawlers is indicated in Fig. 2. Fig. 3 illustrates the relative contribution of tonnage class 2 and 3 vessels to the total catch of Danish and Scottish seiners. Catches by tonnage class 3 vessels have comprised about $75 \%$ of the catch of all Danish and Scottish seiners since 1974.

SAMPLING OF CANADIAN LANDINGS IN THE 1970's

Table 8 indicates the level of sampling of the Canadian landings of this stock in the 1970's. The number of samples taken generally increased in 1976 and has remained at this higher level. However, although gillnets may account for at least $30 \%$ of the catch, the number of samples from the gillnet landings is less than those of otter trawl and Danish seine landings. A greater number of samples from the gillnet landings would be desirable in order to reflect more accurately removals at age from this stock.

Table 9 indicates the mean length and mean age of the cod in the landings of each gear. Cod caught by gillnets and long- and hand-lines were generally older than those caught by otter trawls and Danish and Scottish seines. In a comparison of the otter trawl landings, there was no marked difference in the mean length and mean age of cod landed in the three intervals. Cod landed in the January to April period in this stock were of similar size and age to those landed in the May-August period. Cod landed in the May-August period were slightly larger and older than those landed in the September-December period, but the difference was not pronounced.

Tables 10 and 11 indicate the mean length and age of cod caught by otter trawlers over 150 GRT in the winter 4TVn fishery since 1973. Vessels greater than 100 feet in length were excluded from Div. 4T from 1976-78, and thus no samples were available. In 1973 and 1974, the mean length and age of cod landed in Div. 4T in December were less than those
in the landings of smaller otter trawlers in the same period (Tables 9 and 10). In 1975 there were no samples from landings of otter trawlers less than 150 GRT in the September to December period. Large otter trawlers were readmitted to Div. 4T in 1979. Samples from landings in the November-December period in 1979 indicated that larger trawlers caught similar-sized and aged fish as compared with otter trawlers and longliners less than 50 GRT (Table 10.)

A comparison of the mean length and age of cod landed by otter trawlers over 150 GRT in the winter Div. $4 V n$ fishery (Table 11) with those of all otter trawler May-August landings in Div. 4T in the same year reveals no consistent pattern. There is no evidence that large Canadian otter trawlers in this fishery catch younger or smaller fish than smaller otter trawlers in the May-August fishery in Div. 4T.

ABUNDANCE OF COD FROM RESEARCH SURVEYS

The abundance of cod as derived from the fall groundfish cruises in Div. 4T is indicated in Table 12. The $4+, 5+, 6+$ and $7+$ cod are illustrated in Figure 4. The number of $4+$ has increased by a factor of 2 between 1977 and 1978 and again between 1978 and 1979. This large increase in $4+$ numbers is presumably accounted for by the large size of the recruiting year-classes of 1973, 1974 and 1975. The 1976 year-class also appears to be larger than those before 1973, and the 1977 year-class may equal the 1975 year-class in abundance. The abundance of the 1977 year-class at age 2 was more than twice as large as any other year-class in the research surveys. Mortalities estimated by examining fully recruited age groups indicated that fishing mortality was high through the middle 1970's but has been declining recently.

## CATCH PER UNIT EFFORT

Commercial catch per unit efforts were considered for Canadian otter trawl tonnage classes 2, 3, 4 and 5 and Canadian, Danish and Scottish seiners tonnage class 2 and 3. Otter trawlers account for over $50 \%$ of the Canadian catch (Table 6, Fig. 2), and Danish and Scottish seiners account for an increasing proportion of the Div. 4T catch in the late 1970's. For otter trawlers, tonnage class 5 vessels have accounted for an increasing portion of the trawlers' catch, as has tonnage class 3 for the seiner catch. To estimate the catch per unit effort for each tonnage class, the directed catch and effort were taken for a three-month period that usually accounted for a majority of the catch. For tonnage classes

2 and 3 of both otter trawlers and Danish and Scottish seiners, this period was May, June and July. For tonnage classes 4 and 5, this was January, February and March. The catch per unit efforts for the four tonnage classes of otter trawlers are indicated in Figure 5 and Table 13 and those for Danish and Scottish seiners are shown in Figure 6 and Table 14. No effort data were available for tonnage class 2 otter trawlers in 1979, with most of these vessels based in Quebec. Figure 7 illustrates the catch per unit effort based on the stratified random survey design. These data indicate that catch per unit effort has been increasing since 1975.

Table 15 shows the correlations between the otter trawl CPUE's and research CPUE and research 4+ numbers. The trends in catch per unit effort of tonnage class 3 are the only ones that are similar to those of the research data. Table 16 indicates the same correlations for tonnage class 2 and 3 Danish and Scottish seiners. Again, only tonnage class 3 agreed with the research data, but this was only between commercial CPUE and research $4+$ numbers. The catch per unit effort of tonnage class 3 trawlers and seiners appears to be the most representative in changes of abundance in the cod.

The level of foreign catch of this stock has changed markedly over time. Gray (MS 1979) indicated that the foreign catch has tended to be of smaller cod and that the amount of catch may have been under-reported. Fishing gears have also changed in the Canadian fishery. Gray (MS 1979) concluded that it was not possible to develop an average effort index that adequately reflected the fishery that could be used to adjust fishing mortalities.

## REMOVALS-AT-AGE

Samples of the commercial landings of otter trawlers, seiners, gillnets and handlines were available. Removals-at-age were estimated by taking removals at age by that gear and weighting by the catch in a fourmonth interval when sufficient samples were available. Larger intervals were used when sampling was less intensive. Removals-at-age were calculated in this manner for 1979 and 1978, the 1978 values having been based on preliminary nominal catch data. The rest of the removals-at-age table was taken from Lett (MS 1978), except for 1976 and 1977 which were taken from Gray (MS 1979). The removals-at-age data in Table 17 formed the basis of the cohort analysis.

The same weighting of samples yielded mean weights-at-age in the commercial fishery (Table 18). The mean weights of ages 3,4 and 5 are higher than the mean weights of all age 3, 4 and 5 in the population because these ages were only partially recruited to the commercial gear. Table 19 indicates the catch-at-age divided by the research abundance estimates, as this may be indicative of partial recruitments to the commercial fishery.

## COHORT ANALYSIS

A cohort analysis was conducted by using the removals-at-age data and with the 1979 fishing mortality and selectivity pattern adjusted so that the analysis agreed with the research and commercial CPUE and the research survey data concerning the strength of the recruiting yearclasses (Table 20). The abundance of each year-class at ages 1, 2 and 3 in the research cruise estimates relative to the mean for that age was averaged to provide an index of the year-class size to correlate with estimates of age 3 cod from cohort analysis. This relationship is shown in Fig. 8 and the correlation coefficient was $0.92\left(r^{2}=0.85\right)$.

The accuracy of the cohort was investigated in several ways. The abundance of cod in the 1979 research survey showed a two-fold increase over that of 1978. However, there appears to be a curvilinear relationship between actual abundance and abundance derived from the research surveys, with research surveys possibly overestimating actual increases in abundance. Therefore, more weight was given to the 1976 to 1978 points in fitting final relationships. One relationship examined was the number of age 4 cod in the cohort and in the research surveys. This relationship is indicated in Fig. 9, with the correlation coefficient 0.95 including the 1979 point. Another relationship investigated was between cohort age 4+ numbers and research age 4+ numbers (Fig. 10). With 1979 included, the correlation coefficient was 0.95, and 0.97 without 1979. A final relationship involving the research data was between age $5+$ cohort numbers and age 5+ research (Fig. 11). With 1979 included, the correlation coefficient was 0.91 , and 0.97 without. From these relationships, it is apparent that there is good agreement between the cohort and research numbers.

A relationship between fishable biomass (numbers $x$ partial recruitment $x$ weight) and catch-per-unit effort of tonnage class 3 seiners and trawlers was investigated. Fishable biomass from 1967 to 1978 was calculated by applying the partial recruitments and weights-at-age from Gray (MS 1979) to numbers-at-age in the cohort. Fishable biomass for 1979 was determined by applying the weights and partial recruitments in this analysis to the 1979 numbers-at-age. The relationship between CPUE of tonnage class 3 Danish and Scottish seiners and fishable biomass is indicated in Fig. 12, and the correlation coefficient of this relationship was $r=0.90\left(r^{2}=0.81\right)$. The 1979 point was very close to the
regression line. The relationship between CPUE of tonnage class 3 otter trawlers and fishable biomass is indicated in Fig. 13, with the correlation coefficient being $r=0.80\left(r^{2}=0.64\right)$, with the 1979 point excluded. The 1979 point was off the regression line, with the CPUE unusually high. The 1979 CPUE was 2.7 times greater than that of 1978 (Table 13), and due to the preliminary nature of the 1979 data, must be evaluated with caution. The analyses concerning the precision of the cohort are summarized in Table 21. The regression of numbers at age 3 from the cohort on the recruitment index predicts over 150 million fish at age 3 in 1980. For projections, the 1977 year-class was set at 150 million at age 3, below the size of the 1975 year-class.

## YIELD PER RECRUIT

A Thompson-Bell yield analysis was conducted on the weights and partial recruitments in Table 18. This gave a yield per recruit of 0.76 kg at $F_{0.1}$ of 0.195 and 0.82 kg at $F_{\max }=0.320$.

GROWTH

To determine if instantaneous growth rates were dependent upon population biomass, I determined instantaneous growth rates as determined by changes in weight of ages 5 to 9 and population biomass of ages $3+$ from 1958 to 1978. Biomass was determined by using the weights-at-age from the September research cruises, numbers at age in the stock from 1967 through 1978 from Gray (1979) and numbers-at-age from 1958 through 1966 from Lett (1978).

Mean instantaneous growth rates of ages 5 to 9 were inversely related with population biomass ( $r=-0.64, \mathrm{df}=20, \mathrm{P}<0.01$ ). To smooth out sampling irregularities and better illustrate trends, I examined the relationship between the three-point running averages of biomass and growth rate and found a stronger correlation ( $r=-0.76, \mathrm{df}=18, \mathrm{P}<0.01$ ).

With population biomass implicated as having an effect on growth rate, a method to predict future growth rate changes was investigated because changes in weights-at-age can have an impact on projected total allowable catches. A multiple regression model was fitted by investigating changes in age-specific instantaneous growth rates of ages 3 to 9 that were derived by sampling the landings of otter trawlers from May through August from 1958 to 1978. Instantaneous growth rates greater than 0.45 for ages 5, 0.35 for age $6,0.30$ for ages 7 to 9 , and negative rates were considered an artifact of poor sampling and were excluded from the analysis. The model fitted was:

$$
G=b_{1} W+b_{2} W^{2}+b_{3} \ln B+b_{4} \ln W X B+k
$$

$G=$ age - specific instantaneous growth rate in one year
W = weights in kg for each age
$B=$ biomass of cod in metric tonnes
$K=$ regression constant.
This analysis yielded:

| Variable | Co-efficient |  | S. E. |
| :---: | :---: | :---: | :---: |
| $W$ | 0.784 |  | $\underline{t}$ |
| $W^{2}$ | -0.094 | 0.156 | 5.02 |
| $\ln B$ | 0.689 | 0.023 | -4.12 |
| $\ln$ WXB | -0.810 | 0.117 | 5.90 |
| K | 1.091 | 0.107 | -7.60 |

The multiple correlation was $0.88\left(R^{2}=0.77\right)$ and the regression was highly significant ( $F=68.13, \mathrm{df}=4,98, \mathrm{P}<0.0001$ ).

The mean weights-at-age for Div. $4 T$ cod in the September research cruises are shown in Table 22, and those of the May through August otter trawl fishery are shown in Table 23. The otter trawl data indicates that mean weights of fully-recruited fish have been declining the past three years and the research data indicates that mean weights of age 3 to 6 cod decreased from 1978-79.

## PROJECTIONS

Projections were conducted from the 1979 numbers-at-age in the cohort analysis. The relationship between cohort age 3 numbers and the recruitment index predicted a 1979 recruitment of 100 million and a 1980 recruitment of 150 million. The 1981 recruitment was assumed to be 100 million, but this will have little bearing on the TAC due to the low partial recruitment of age 3 cod. These values were input as the estimated recruitments from 1979 to 1981.

Projections were run under the assumption that the weights-at-age and partial recruitment in 1979 will remain constant until 1981. Two projections were run, with one incorporating a 1980 TAC of 54,000 tonnes and the other an $\mathrm{F}_{0.1}$ fishing mortality. The results of these projections are indicated in Table 24.

An example projection incorporating biomass-dependent growth.
A projection incorporating the effects of population biomass on growth rate was conducted by predicting future weights-at-age from the growth rate equation in the previous section and the 1979 weights-at-age in Table 18. For each year from 1980-85, the procedure was to calculate weights-at-age, population biomass, yield per recruit and associated $\mathrm{F}_{0.1}$. Partial recruitments were assumed to remain constant from 1980-85. Recruitments were assumed to be 100 million in 1979,150 million in 1980,100 million in 1981, and 70 million from 1982-85, the geometric mean of recruitment from 1967-78. Two projections were done to illustrate the differences in TAC by assuming constant weights-at-age and biomass-dependent changes in weights-at-age.

Table 25 illustrates the results for the fixed parameter projection. A TAC in 1980 of $54,000 \mathrm{mt}$ results in a fully-recruited fishing mortality of 0.21 . A projection incorporating biomass-dependent growth was also run, under the assumption of a TAC of 54,000 tonnes in 1980 and a fishing mortality of $\mathrm{F}_{0} .1$ from 1981-85. Age 3 cod were assumed to be a constant weight of 0.35 kg . The parameters used for each annual projection are indicated in Table 26. The results of the biomass-dependent weights-atage projection are shown in Table 27. A TAC in 1980 of 54,000 tonnes results in a fully-recruited fishing mortality of 0.25 . The catch biomasses at the $F_{0.1}$ fishing mortality range between $10,000-30,000$ tonnes less in the biomass-dependent growth projection than in the fixed parameter projection. The weights-at-age in the commercial fishery in 1980 will have to be carefully investigated for next year's assessment in order to provide updated advice for 1981.

## DISCUSSION

The comparison of the fixed parameter and biomass-dependent growth projections to 1985 are for illustrative purposes only and are not intended, in either case, to be representative of the actual conditions experienced in the future. The empirical statistical relationship between growth rate and population biomass has not been validated, and it has not been established that weight-at-age 3 is constant as assumed in the projection. It seems reasonable that partial recruitment to the fishery is likely to vary with
growth rate rather than remain constant as assumed. The illustration simply indicates that biomass-dependent growth could result in even short-term projections using a fixed parameter model being in error by 10 to $20 \%$. However, in relation to 1981, errors in assessment of the current status of the stock are probably of a similar magnitude, and the difference between the results of the two projections in the short term may not be meaningful. It would be useful to investigate management strategies other than fishing at $F_{0.1}$ in relation to maximizing long-term catches from a stock when growth rate is dependent upon stock biomass.

## ACKNOWLEDGEMENTS

I would like to thank Bev Fowler and Albert Vromans for their conscientious help in compiling many of the data series used in this analysis.
