#### Abstract

Research vessel survey population estimates and Canadian tonnage class 5 average catch per unit of effort during the months of January to April were used to fine tune ages 5 and older VPA mean numbers and biomass. A fully recruited 1980 fishing mortality of $F=0.225$ was considered to best represent the age 5 and older stock status. Year-class size at ages 4 and 3 in 1980 were adjusted by regression with an index of year-class size from R.V. surveys while year-class size at age 2 was estimated from a relationship between year-class size at age 1 and the age 7 and older biomass during the year of spawning. The $1982 \mathrm{~F}_{0.1}$ catch is estimated to be $53,700 \mathrm{mt}$.

Résumé
Les estimations de populations dérivées des levées de navires de recherche et les prises par unité d'effort moyennes des bateaux canadiens appartenant à la classe de tonnage 5 durant les mois de janvier à avril ont été utilisés pour ajuster les nombres moyens et les biomasses de 5 ans et plus de l'APV. Une mortalité par pêche en 1980 de 0.225 sur les âge pleinement recrutés a semblé donner la meilleure représentation de l'état du stock de 5 ans et plus. Les nombres de poissons de 3 et 4 ans en 1980 ont été estimés par régression avec un indice dérivé des levées des navires de recherche alors que le nombre de poissons de 2 ans a été estimé à l'aide d'une relation entre la taille des classes d'âge à 1 an et la biomasse des poissons de 7 ans et plus durant l'année de ponte. La capture au niveau $\mathrm{F}_{0,1}$ en 1982 est estimé à $53,700 \mathrm{tm}$.

## Introduction

This stock complex had been under quota management since 1973 when ICNAF set the first TAC at $60,500 \mathrm{mt}$. Assessments of the stock status at the time (Halliday, 1972) indicated that the fishing mortalities were slightly above $F_{\text {max }}$, that incoming year-classes generally appeared to be below average and that a $60,000 \mathrm{mt}$ TAC for 1973 was "higher than that desirable for this stock" (Halliday, 1972 p.6). This statement appears to have been appropriate and the TAC was undercaught in 1973-1974 and 1975 (60,000 mt for 1974 and 1975).

The stock complex was assessed again in 1975 (Halliday, 1975) using newly recalculated removals at age for Spain and the USSR which indicated recruitment to the fishery at a much younger age than was previously assumed based on the sampling of Canadian catches. The calculations showed that a $60,000 \mathrm{mt}$ TAC in 1976 would generate fishing mortalities substantially above the estimated $F_{\max }$ and that the $1976 \mathrm{~F}_{\max }$ yield would be between 28,000 and 31,000 mt while the $F_{0.1}$ catch would have been between 17,000 and $19,000 \mathrm{mt}$. The 1976 TAC was set at $30,000 \mathrm{mt}$ and again undercaught.

The 1976 assessment of $4 V$ sW cod indicated that:

> "since 1971 , fishing mortality rates have exceeded $F_{\max }=0.35$. However the observed levels of fishing mortality were not sufficient to explain the rapid decline in stock size in recent years, the major cause being the recruitment to the fishery of the poor 1971 to 1973 year-classes. In view of the large silver hake fishery conducted in this area with small meshed trawls during the period when the cod stocks declined, the Subcommittee examined the consequences of relatively small by-catches of young cod (ages 1 and 2) in the silver hake fishery on the subsequent recruitment of cod. It was estimated that by-catches of about 4,000 mt annually, equally divided between ages 1 and 2 fish, explained the reduced recruitment of cod observed in recent years, and that by-catches of 10,000 mt of age 1 fish could virtually eliminate the cod stock." (ICNAF Redbook 1976, p.87).

Canada extended its jurisdiction over fisheries to 200 miles as of January 1, 1977 and CAFSAC (Canadian Atlantic Fisheries Scientific Advisory Committee) was created soon afterwards to, among other things, provide scientific advice to the Atlantic Fisheries Management Committee on the management of all stocks of interest or potential interest to Atlantic coast fishermen. The CAFSAC 1977 Groundfish Subcommittee Report (Appendix I of Advisory Document 77/3) states that:
"Reasons for the decline of this cod stock are not yet fully known. Two possibilities were considered. First, the silver hake fishery in 4VWX might take young cod as by-catch. Second, silver hake may predate on young cod. The correlations between cod numbers at age 1 and effort in the silver hake fishery that was shown in the 1976 assessment of this stock was not as strong when new data were added. No significant relation was found between cod numbers at age 1 and silver hake biomass" (p.34).

The Subcommittee recommended that the 1978 catch be kept to the lowest possible level and and that under no circumstances should the catch be allowed to surpass 7,000 mt (Ibid. p. 34).

For the first time since the stock had been under quota management, the 1977 catch exceeded the TAC and the Canadian catch showed a slight increase over 1976.

In the 1978 assessment it was found that:
"research survey estimates showed an overall increase in numbers in 1977. However, the age distribution showed lower than usual percentages of one and two year olds. Hence it was assumed that the change in numbers was due to a change in availability and that the data emphasized the lowered recruitment. A CPUE index was developed using data up to 1976 for Spanish pair trawls combined with data to the present for Canadian otter trawls. The CPUE showed an increase in 1977 but, due to the extreme change in the fishery, it was felt that this figure was not comparable to past values" (CAFSAC Advisory Document 78/2, Appendix 3, p. 96).

All indications were that recruitment had seriously dropped and although the Subcommittee felt that it would be optimal to close the fishery, it recommended that under no circumstances should the catch be allowed to exceed 7,000 mt.

It now appears that the stock had started to recover in 1977 and that the 1978 TAC was probably below the optimal level. This led to misreporting of catch location by Canadian fishermen to comply with the existing TAC,'s. When appropriate corrections were made to catch locations, the 1978 catch was estimated to be $25,405 \mathrm{mt}$, substantially above the $7,000 \mathrm{mt}$ TAC.

In the 1979 analysis more weight was given to research survey population estimates since the Canadian commercial catch rates were believed to be unreliable due to misreporting while the Spanish catch rate series had ended in 1976. Closer examination of the Spanish data showed "consistency in apportionment of catches to ICNAF Divisions which suggests arbitrary assignment of catches which were initially reported in too little detail "(CAFSAC Advisory Document 79/7, App. I, p.38). However the Spanish catch trends in 4VsW agreed well with R.V. surveys data and other countries CPUE so the Subcommittee did not see any "reason to disbelieve that the catch rate trends of Spanish pair trawlers in Division $4 V$ sW are an accurate reflection of their fishing success "(Ibid p.38). There was also suspicion, but no evidence, that discarding of small cod may have occurred in the Spanish fishery.

Data from the International Observers Program indicated that by-catches of cod in the small mesh fisheries had been underestimated and corrections were made to the removals at age matrix. The results of the assessment indicated an F0.1 catch of $42,000 \mathrm{mt}$ in 1979 and $44,000 \mathrm{mt}$ in 1980. However there were considerable uncertainties in the assessment (variability of R.V. survey estimate, 1978 catches etc.) and, in order to further speed up the recovery of the stock, TAC's of $30,000 \mathrm{mt}$ and $45,000 \mathrm{mt}$ were set for 1979 and 1980 respectively. The catch exceeded those values by $10,000 \mathrm{mt}$ in 1979 and by 4,000 mt in 1980.

There is no indication of substantial misreporting in both 1979 and 1980 and the Canadian catch rates will thus be used in the following analysis in conjunction with research vessel survey data.

## Nominal catches:

Table 1 shows the 4VsW cod nominal catches by country and NAFO Divisions and Figure 1 shows the total nominal catches since 1958. Until 1976, Spain was the main harvester of that stock complex, catching on the average $33,000 \mathrm{mt}$ a year or $58 \%$ of the total nominal catches. Canada followed with $16,500 \mathrm{mt}$ caught annually or $30 \%$ of the total. The USSR ( $3,300 \mathrm{mt}$ or $6 \%$ ), France ( $1,900 \mathrm{mt}$ or $3 \%$ ) and Portugal (1,000 mt or $2 \%$ ) followed. The average yearly catch by other countries was $1,000 \mathrm{mt}$ annually or $2 \%$ of the total. The maximum catch was reported in 1968 ( $80,425 \mathrm{mt}$ ) and the lowest one in 1977 ( $10,390 \mathrm{mt}$ ). The 1958 to 1972 average is close to $61,000 \mathrm{mt}$. As indicated in the introduction the 10 w catches between 1973 and 1977 are believed to be due to decreased recruitment following by-catches of young cod in the silver hake fishery and the pre-1972 average catch is thought to be more representative of expected yields from that stocks complex.

Since 1977 the fishery has been almost solely Canadian and the catch by other countries amounted to only 386 mt of $49,164 \mathrm{mt}$ caught in 1980 . The total nominal catch has steadily increased from $10,390 \mathrm{mt}$ in 1976 to close to 50,000 mt in 1980. On the average, since 1958, $48 \%$ of the total has been caught in 4 Vs and $52 \%$ in 4 W . The catches in 4 Vs did not show any trend until 1973 when they started to decline; this trend continued up to 1977 when the stocks started to increase again. The catches in 4W increased steadily from 1958 to 1963 then declined to 1967 with a hump in 1966 and remained relatively stable up to 1974 when the decline observed in 4Vs became apparent in 4 W with a lag time of one year. The trend afterwards is the same as in $4 V$ s except that there is a decrease from 1979 to 1980. From 1974 to 1979 the catches in 4W have consistently been higher than those in 4 V .

For the Canadian fishery, trawlers have generally caught the major portion of the catch (Table 2). Except for a few years, between 1958 and 1961, and in 1978 trawlers took in excess of $90 \%$ of the 4 V s catch while in 4 W the catch was almost equally divided between trawlers and other gears. Of the 48,778 mt caught by Canada in $1980,72 \%(35,084 \mathrm{mt})$ were caught by trawlers, $19 \%$ (9,139 $\mathrm{mt})$ by longliners and $8 \%(3,763 \mathrm{mt})$ by Danish and Scottish seines. Various other gears caught $2 \%$ ( 792 mt ) of the total 1980 provisional nominal catches.

## Removals at age:

Data collected by international observers on USSR vessels fishing for silver hake and squid on the Scotian Shelf showed that the USSR was underestimating the by-catches of cod in those fisheries by an average ratio of 2.66 for 1977-1978 (Gray, 1979). As mentioned earlier, this led in the 1979 assessment (Gray, 1979) to a correction of the catch at age used in previous years to account for suspected under-reporting for years prior to 1977. Provisional data were used for these calculations and the average by-catch ratio has been recalculated with final data.

In 1977, the by-catch ratio of cod by USSR vessels with observers on board was 0.006 in the silver hake fishery and 0.002 in the squid fishery. For that year, the USSR reported a total nominal catch of 97 mt of cod in Divisions 4 Vs and 4 W . If it is assumed that the by-catch ratios calculated from boats with
observers are the same on boats without observers and given the reported silver hake nominal catches of $27,351 \mathrm{mt}$ and the squid catches of $18,812 \mathrm{mt}$, it is calculated that the USSR caught 202 mt in 1977, giving an under-reporting factor of 2.1. The by-catch ratios for 1978 were 0.0043 for silver hake and 0.0044 for squid for boats with observers. Given the reported nominal catches of silver hake $(42,202 \mathrm{mt})$ and squid $(12,434)$, it was calculated that the USSR caught 236 mt of cod compared with the reported nominal catches of 218 mt . The 1978 underreporting factor would thus have been 1.1 and the average factor for 1977-78 would be 1.6. It is not known at this time, and will probably never be known, what was the real under-reporting factor of cod catches by the USSR for years prior to 1977 and it is not known either if a factor of 1.6 would be more appropriate than the previously used factor of 2.66. However given the results of the calculations, a new catch at age matrix was calculated using the former value (Table 4). It should be noted that other corrections could happen in the future after a planned in depth study of the international observers data base has been done.

When Halliday (1975) recalculated the USSR catch at age he assumed that the average weight of the fish in the catch was 0.415 kg and that, for years prior to 1973 , the age distribution of the catch was:

| Age | 1 | 2 | 3 | 4 | 5 |
| ---: | ---: | ---: | ---: | ---: | ---: |
| Proportion | .08 | .51 | .33 | .06 | .02 |

From 1973 onwards USSR length frequencies were aged with Canadian summer R.V. surveys age-length keys.

From Halliday's (1975) and Gray's (1979) data, both the USSR uncorrected and other countries (without USSR) catch at age were recalculated. The USSR data were then multiplied by 1.66 and added up to matrix without USSR catch at age to obtain the new removals at age matrix shown in Table 4.

Table 3, shows the Canadian samples collected for that stock complex since 1979. The 1980 catch at age was obtained by constructing quarterly age-length keys from otter trawl samples and applying them to the quarterly nominal catches. A total of 52 otter trawl samples were collected in 1980, 17 in the first quarter, 7 in each of the second and third, and 21 in the fourth quarter. A yearly age-1ength key was made with the four seines (Danish and Scottish) samples and applied to nominal catches by those gears and the four longline samples were used in the same manner. The total catch at age was obtained by prorating the sum of these catches at age for unsampled catch. The 1979 catch at age presented by Maguire (1980) was prorated upwards to account for the 1979 revised total nominal catch figure.

Table 5 shows a matrix of removals at age by Canadian otter trawlers since 1960. From 1960 to 1977 all otter trawl samples were combined on a yearly basis and applied to the total Canadian otter trawls nominal catches. The same $A$ and $B$ parameters of the length-weight relationship ( $A=0.0071$ and $B=3.084$ ) were used for that period. For 1978 to 1980, yearly A and B parameters from the summer R.V. surveys were used and there were enough samples in those years to
construct quarterly age-1ength keys and apply them to quarterly nominal catches.

## Weights at age:

Weights at age (Table 6) for 1966 to 1978 were available from unpublished data sheets (D. Gray pers. comm.), the 1979 from last year's assessment and the 1980 were calculated from this year's sampling data. The average weights at age for 1966 to 1980 were used for 1958 to 1965.

Stock size indices:

Research vessel surveys
Stratified random groundfish surveys have been conducted during the summer since 1970 on the Scotian Shelf. As mentioned in the introduction these data were most important in the recent assessment of the stock complex. Tables 7a and 7 b show the average number caught per set per stratum for both of 4 Vs and 4 W . High catches in one set of each of stratum 58 and 59 in 1973 made the population estimate for that year out of proportion with the neighbouring years results (Table 8a). The population size was re-estimated without those two sets and the new population size estimates are shown in Table 8 b for 4 V s and 4 W combined while Table 8c and 8d show the corrected data for $4 V \mathrm{~s}$ and 4 W separately. Figure 2a shows the R.V. population estimates since 1970 for ages $3+, 4+$ and 5+. There was a general decline from 1971-72 to 1975 and the rebuilding started in 1976. Ages 3 and older increased very rapidly to above the 1971 level in 1978 followed by a slight decline in 1979 and stabilizing at the 1979 level in 1980. Ages 4 and older show a slower increase to 1978 and stability afterwards while the ages 5 and older show increases in 1976 and 1977 then a slight decline in 1978, a rapid increase in 1979 above the 1971 estimate and the 1980 level is slightly above 1979.

The same data for 4Vs and 4W separately are shown in Figure 2b. The 4W population estimates have remained relatively stable from 1970 to 1975, then rapidly increased to 1978 for ages $3+$ and 4+ followed by declines in 1979 and 1980. For ages 5 and older the increase is to 1979 and the 1980 estimate is approximately at the 1978 level. There was a very pronounced decline from 1971-72 to 1974-75 in 4Vs, followed by an increase to 1977, a dip in 1978 and then a continuous rapid increase to 1980. It is interesting to note that the predominance in contribution to the catch of 4 W over 4 Vs observed for the period 1973 to 1979 (Table 1) is generally parallelled by the $3+$ population estimates (Figure 2b). The decline in population estimates since 1978 in 4 W would tend to support the hypothesis that in recent years the fishing fleet has exerted a high fishing effort on relatively localized but dense schools of fish (CAFSAC Advisory Document 79/7, App. I. p.43) as most of the fishing occurred on Middle Ground in both of 1978 and 1979.

An index of year-class size at age 3 and 4 was developed from the R.V. survey population estimates at age by dividing the yearly population estimates
by the averages from 1970 to 1980 for each respective age. The sum of those ratios for ages 2 and 3 was taken as an index of year-class size at age 3 and the sum of $3+4$ as an index of year-class size at age 4 (Table 9 and Figure 3). Both indices indicate the same general trends except that the 1972 year-class appears strong at age 3 but below average at age 4. This is due to a high population estimates of 2 year olds in 1974. It appears that the above average 1968 year-class has been followed by a succession of four weaker than average year-classes. The 1973 year-class would be of moderate strength at age 4 while the 1974 and 1975 year-class at the same age would be above average and the 1976 slightly below average but stronger than the 1969 to 1972 year-classes. The same pattern is indicated by the index at age 3 and the 1977 year-class would also be slightly below average.

## Commercial catch per unit of effort

Since this fishery is now almost $100 \%$ Canadian, the analysis of commercial catch rates was limited to Canadian vessels. Tonnage classes 2 and 3 nominal catches have historically been small and apparently randomly distributed over the year. Due to their low contribution to the total catches, their catch rates were not considered to be useful as an index of stock size fluctuations. Tonnage classes 4 and 5 boats took the main share of the Canadian catch but since Gray (1979) found that TC4 catch rates did not correlate well with R.V. survey population estimates, TC5 catch rates nor Spanish pair trawlers catch rates, the CPUE analysis was limited to Canadian TC5 otter trawlers. This fleet usually took the bulk of its catch in the beginning and end of the year but more so in the beginning. The averages of January to April catch rates were thus calculated for TC5 trips in which cod represented $50 \%$ or more of the total catch by dividing the total cod catches by total effort. Gray (1979) mentions that "In 1974-75 the Canadian tonnage class 5 vessels changed from a Western traw to an Engel trawl with an estimated" (by the industry)" increase in efficiency of $30-40 \%$ ". Since the change occurred over a two year period, it was assumed that half the vessels changed to an Engel trawl in 1974 (C/E multiplied by 0.825) and the other half in 1975 (C/E multiplied by 0.65 ) and that the average increase in efficiency was $35 \%$, the middle point of the figures mentioned by the industry. Less than 400 mt of cod were caught by TC5 vessels from January to April of both 1965 and 1966 and the catch rates for those years are not believed to be representative of the stock size; they were thus excluded. The CPUE data are shown in Table 10 and Figure 4. The TC5 catch rates show a general decline from 1967-68 to 1976, with a little hump in 1972-73, and a steady increase to 1980 surpassing in 1979 the highest catch rates levels previously recorded in 1968.

A catch per unit of effort at age matrix was developed from the Canadian otter trawl catch at age matrix (Table 5) and an index of relative effort (Table 10) computed by dividing the yearly total Canadian otter trawl nominal catches by the yearly TC5 catch rates during January to April. The CPUE at age matrix (Table 11) was obtained by dividing the catch at each age by the yearly relative effort index. Similar results could have been achieved by multiplying the yearly Canadian otter trawlers percentage catch at age by the TC5 catch rates in January to April. The only difference between such a matrix and Table 11 would be a scaling factor. These data (Table 11) indicate that the Canadian otter trawl fleet generally exploited mainly ages 4, 5 and 6 . The various ages
indicate different relative sizes for the year-classes considered e.g. the 1971 year-class shows up as the strongest observed at age 3 but at older ages it is one of the weakest. This may be due to the inherent variability of catch at age data but similar observations can be made for the 1969 and 1970 year-classes. This would support the hypothesis that the decrease in stock size observed in the mid-seventies was due to overexploitation of average or above average yearclasses at young ages. At age 4, the 1966, 1967, 1969, 1971, 1972 and 1973 year-classes are weaker than average while at age 5 and 6 every year-classes from the 1963 year-class to the 1972 year-class inclusive would have been smaller than average and all subsequent would have been stronger than average, the 1974 year-class being the strongest. At age 7, the 1973 year-class is the strongest followed by the 1968 year-class.

Sequential population analysis
Total instantaneous mortality rates (Z) were calculated from the R.V. population estimates (Table 8b) and from the Canadian otter trawl catch per unit of effort at age (Table 11) by taking the ratio of the sum of the population estimates of ages 5 to 11 in year $t$ to the sum of the population estimates of ages 6 to 12 in year $t+1$ for the surveys and the ratios of the sum of CPUE at ages $5-15$ in year $t$ and 6-16 in year $t+1$ for the CPUE at age. The average $Z$ value for 1979-80 was . 507 for the survey data and 0.406 for the otter traw 7 CPUE at age data, giving an average $Z$ of 0.457 or $F$ of 0.257 . This value was used as the 1980 fully recruited $F$ to run a first VPA with partial recruitment multipliers on ages 2 to 4 similar to those used in last year's assessment (Maguire, 1980), and full recruitment at ages 5 and older. The resulting 1979 fishing mortalities at age were decreasing after age 6. A three point median smoothing (Smith, 1981) applied to these $F^{\prime}$ s showed a continuous decline of $F^{\prime} s$ from age 7 to 11, increases at ages 12 and 13, decreases at 14 and 15 and an increase at age 16. To reconcile the decrease in F's from ages 7 to 11 with the subsequent increases and decreases the 1980 partial recruitment vector was defined as follows:

| Age | 2 | 3 | 4 | 5 | 6 | 7 | 8 | 9 | 10 | 11 | 12 | 13 | 14 | 15 | 16 |
| :--- | ---: | ---: | ---: | ---: | ---: | ---: | ---: | ---: | ---: | ---: | ---: | ---: | ---: | ---: | ---: |
| PR | .0018 | .1135 | .60 | 1.0 | 1.0 | .85 | .70 | .60 | .5 | .5 | .5 | .5 | .5 | .5 | .5 |

This partial recruitment vector was used to tune VPA ages 5 and older mean numbers (as an approximation to mid-year numbers) with the R.V. surveys ages 5 and older population estimates and VPA ages 5 and older beginning of the year biomass with Canadian tonnage class 5 catch per unit of effort in January to April.

In addition to estimates of fishing mortalities in the last year, VPA requires as input values an estimate of $M(0.2)$ and the fishing mortalities for the oldest age for every year. In every case, a first VPA was run with initial estimates of age $16 \mathrm{~F}^{\prime} \mathrm{s}$, then the yearly average $\mathrm{F}^{\prime} \mathrm{s}$ on ages 6 to 9 were calculated and compared with the previous estimates. If the difference for any of the F's was greater than $\pm 0.001$ another VPA run was made using the yearly average $F^{\prime} s$ on ages 6 to 9 as input values for $F_{16}$. The process was
repeated until the difference between any of the input $F_{16}$ and ages 6 to 9
average $F^{\prime}$ s was smaller than $\pm 0.001$. It took usually between 3 and 5 runs to obtain stable $\mathrm{F}_{16}$.

Runs with 1980 fully recruited $F$ equal of $0.20,0.225,0.25,0.275$ and 0.300 were made, and the results are given in Table 12. The relationship between VPA numbers and R.V. population estimates was calculated excluding the 1970 point since it was an outlier at every starting fishing mortality and also because there were some changes made to the gear used in the survey between 1970 and 1971 (Halliday and Kohler, 1971). The relationships were not very sensitive to changes in the 1980 F's ranging from 0.20 to 0.30 . The best correlations were obtained for both relationships with a 1980 fully recruited $F$ of 0.25 but 1980 fully recruited $F=0.225$ was taken as best representing the stock status based on the close agreement between the 1980 VPA calculated $5+$ biomass and mean population numbers and the values predicted by the G.M. regressions with TC5 catch rates and R.V. surveys population estimates (Fig. 5a-b).

The R.V. index of year-class size at ages 3 and 4 (Table 9) was used to adjust fishing mortalities on those ages by changing the 1980 fishing mortalities at age 3 and 4 to obtain the 1976 and 1977 year-classes calculated by cohort on the G.M. regression line (Figures 6 and 7). Fishing mortalities of 0.026 and 0.163 on ages 3 and 4 respectively were obtained giving partial recruitment multipliers of 0.116 and 0.724 . It should be noted that although the fishing mortalities at ages 3 and 4 were adjusted as the 1980 values were exactly on the G.M. regression line, it is not suggested that these are exact estimates. There are sufficient uncertainties regarding the accuracy of the catch at age matrix that one may be surprised to obtain any relationship with the R.V. population estimates especially since the latter also have relatively high inherent variability.

A plot of year-class size at age 1 versus ages 7 and older biomass during the year of birth of the year-class was then made with the data from the VPA run with the partial recruitment multipliers on ages 3 and 4 obtained above and there appeared to be a relationship between those two variables (Figure 8). There was no evidence for a dome and a Beverton and Holt (1957) stock-recruitment model was fitted to these data by the method of Paulik (1973). This method estimates $1 / R$ and inverting the estimated values of $1 / R$ represents the harmonic mean of expected recruitments at each stock size which tends to be below the arithmetic mean of expected recruitments (Ricker, 1975). Ricker (1975) recommends multiplying the inverse of the expected values by the ratio of the sum of the observed to the sum of the predicted recruitment values. This ratio was 1.0375. From the 1978, 1979 and 1980 ages 7 and older biomasses, the respective year-classes would be approximately 95,116 and 141 million fish. Partial recruitment on age 2 in 1980 was adjusted to obtain a 1978 year-class size at age 1 of approximately 95 million fish while P.R. on age 1 in 1980 was adjusted to obtain a 1979 year-class size at age 1 approximately equal to the geometric mean recruitment from 1958 to 1977 at age 1 (101,287,000 fish).

The resulting VPA population estimates at age are shown in Table 13. There are some differences between the trends when different groups of ages were considered but all age-groupings indicate a decline from the late sixties to mid seventies followed by an increase to 1980. The age 1 and older population went from a high of 445 million fish in 1966 to a low of 244.5 million in 1973,
increasing continuously afterwards to reach 369.9 million fish in 1980 . The ages 2 and older population was at its maximum in 1968 ( 320 million), reached a minimum in 1974 ( 155.7 million) and increased regularly afterwards to reach 269 million in 1980. For ages 3 and ofder the maximum was in 1968 ( 222.7 million), the minimum in 1975 ( 93 million), and the 1980 value is 190.8 million. The maximum ages 4 and older numbers was recorded in 1961 ( 133.6 million) and the stock would have increased from the lowest recorded value of 49 million in 1975 to 139 million in 1980, a slight decrease over the 150 million fish for ages 4 and older estimated in 1979. The 1980 ages 5 and older population estimate is 103 million fish having rapidly increased from an all time 10 w of 26.4 million fish in 1976. The 1980 value is slightly higher than the previously recorded high of 82.7 million fish in 1961. Stock recruitment relationships have seldom been demonstrated and, again, given the uncertainties associated with the catch at age matrix, it is not suggested that one has been demonstrated here. The relationship observed may well be spurious and as more reliable catch at age data accumulate, the relationship may or may not hold.

Table 14 shows the mean population estimates used in calculating the different relationships between VPA population estimates and R.V. population estimates while Table 15 shows the beginning of year population biomass estimates. This last table essentially shows the same patterns as those of Table 13 (population numbers).

It appears that the 1980 fishing mortality is slightly above the 1979 value (Table 16). The average fishing mortalities on ages 6 to 9 has consistently been above $F_{0.1}$ from 1970 to 1976 and was below $F_{\max }$ only in 1970 for that period. The extension of the jurisdiction over fisheries has substantially reduced the fishing mortalities from 0.641 for ages 6 to 9 in 1976 to below 0.20 for the same age groups since 1977.

Figure 9 shows the relationships obtained between VPA year-class size estimates at age 4, 5, 6 and 7 versus the catch per unit of effort of Table 11 at the same ages. These relationships were not used in fine tuning VPA and are only presented as confirmatory evidence that the 1980 fishing mortality and partial recruitment multipliers chosen are consistent with the CPUE at age data set. There is some indication from these figures that the ages 5 and older 1980 fishing mortalites may be slightly overestimated since the last points are always under the G.M. regression lines. This is especially true for the age 5 plot where a regression calculated with the 1963 to 1973 year-classes would predict much higher 1974 and 1975 year-classes than those from VPA in this analysis; 73 and 47 million compared to 51 and 38 million for VPA. As mentioned earlier, however, there is some indication that the behaviour of the Canadian otter trawl fleet has changed in recent years and the CPUE values now obtained may not be directly comparable with previous figures. The relationships are nevertheless indicating that the 1973 to 1975 year-classes are fairly strong compared to earlier ones and that the analysis presented is probably not overestimating the size of these year-classes.

## Yield per recruit

A Thompson and Bell yield per recruit calculation was made with the partial recruitment multipliers and weights at age of Table 17. Maximum yield per recruit ( 0.681 kg ) occurred at $F_{\max }=0.395$ and the yield at
$F_{0.1}=0.234$ is 0.640 kg per recruit, $94 \%$ of the yield at $F_{\text {max }}$, but the catch rate at $\mathrm{F}_{0} .1$ would be approximately 1.6 times that at $F_{\text {max }}$. The $F_{0.1}$ value of 0.234 is slightly above the common $F_{0.1}=0.2$ value for cod in the northwest Atlantic. However this fishing mortality of 0.234 is applied only on fully recruited ages (5 and 6). Fishing at $\mathrm{F}_{0.1}$ in 1982 with partial recruitment multipliers as in Table 17 would generate a weighted (by population) average $F$ of 0.199 on age 5 to 16 , a value identical to the usually accepted value of 0.2 . Figure 10 shows the yield per recruit curve.

## Projections:

Projections to 1982 fishing at $\mathrm{F}_{0.1}$ were made assuming that the 1981 catch would be equal to the $50,000 \mathrm{mt}$ TĀC, using the average weights at age observed in the 1980 fishery and assuming that the 1980 and 1981 year-classes will be equal to the geometric mean recruitment for the 1957 to 1976 year-classes (101,287,000 fish). Under these conditions the 1982 catch would be $53,700 \mathrm{mt}$. The contribution of each age to the 1981 and 1982 catches are shown in Table 18.

## Conclusion:

The recovery of this stock complex has been rapid although it is not yet quite complete and it would seem that lower by-catches of young cod in small meshed fisheries combined with substantially reduced fishing mortalities on all age-groups made it possible for that stock complex to increase quickly to population sizes comparable to historical levels. If recruitment levels are maintained, it is expected that catches in the order of the pre-1972 average levels ( $60,000 \mathrm{mt}$ ) could be achieved in the not so far future.

1 The total is the total yearly nominal catch by otter trawlers.
2 C/E corrected for increased efficiency for gear change that occurred in 1974-75. Correction is C/E $\times .835$ for 1974 and C/E $\times .65$ for other years.

3 Fishery was reopended in May so that month is included in the calculations.
