#### Abstract

Landings fram the 4 T herring stock declined fram 270000 t in 1970 to 40500 t in 1980. Recently, the fishery has been sustained mainly by the 1974 year-class. The catch matrix shows a decreasing trend in the proportion of mature fish in the catch ( 6 years old: $91 \%$ in 1969, $22 \%$ in 1980), while no particularly strong recruitment is obvious since the 1974 year-class entered the fishery. An analysis of the catch rate data reveals that for both the commercial inshore and offshore fishery and groundfish research cruises catch rates are at a historical low, except for the Pictou Island fall gillnet fishery. Total mortality coefficients ( $Z$ ) were calculated for fully recruited herring, using different fishing effort indices. All the $Z$ values were above 0.94 between 1979-1980, and averaged 1.40. A new partial recruitment vector, which reflected the increasing contribution from young fish, was estimated and used in cohort analysis. The resulting biamass and population number estimates were correlated with different catch rates, with all the coefficients being above 0.92. Estimated fishing mortality of fully recruited fish has increased fram 0.290 in 1969 to 1.203 in 1980. A Thompson and Bell yield-per-recruit analysis gave a value of $F_{01}=0.331$.

The stock biomass, age 2 to 11, has declined to $54500 t$ in 1980 (weight for the first quarter of the year), 5 percent of the maximum level estimated in 1969.

Résumé

Les captures de hareng du stock 4T ont passé de 270000 t en 1970 à 40500 t en 1980. Récemment, la classe d'âge 1974 a contribué le plus fortement à maintenir la pêche. La matrice des príses à l'âge révèle une diminution dans la proportion capturée des poissons matures ( 6 ans: $91 \%$ en 1969, $22 \%$ en 1980). D'autre part aucune classe d'âge importante n'est apparente depuis l'avènement de la classe d'âge 1974 dans la pêche.

Les taux de capture commerciaux et de recherche, tant dans la peche côtière que hauturière, sont à un niveau historiquement faible, sauf en ce qui concerne la pêche automnale au filet maillant à Pictou.

Les taux de mortalité totale ( $Z$ ) ont été calculés pour les poissons pleinement recrutés, en utilisant divers indices d'effort de pêche. Tous les coefficients de mortalité étaient supérieurs à 0.94 en 1979-1980, avec une moyenne de 1.40 .

Le recrutement partiel a été estimé de façon à tenir compte de l'importance grandissante des jeunes individus dans la capture, et utilisé dans une analyse de cohorte. Les estimations de biomasse et d'abondance en nombre de la population ont été corrélées à divers taux de capture. Tous les coefficients de corrélation étaient supérieurs à 0.92. La mortalité par la pêche a ainsi été estimée à 0.290 en 1969 et 1.203 en 1980, pour. les poissons pleinement recrutés.

Un taux de mortalité $F_{01}=0.331$ a été calculé à l'aide de l'analyse de rendement par recrue de Thampson et Bell. La biomasse pour les poissons de 2 à 11 ans, (pour le premier semestre de l'an) a diminué jusqu'à 54500 t en 1980, soit cinq pour cent de la bianasse maximale estimée en 1969.

Landings of 4 T stocks were reported in NAFO division 4 T and subdivision 3Pn until 1973, after which date most of the catch was recorded in division 4T (Tables 1, 2 and 3). Total landings (4T, 3Pn) attained maximum $(269,721 t)$ and minimum $(35,227 t)$ values in 1970 and 1974 respectively. However, since 1973, the total catch has been relatively stable, averaging 43,690 t. Quota regulations were set in 1975 but, the catches never reached the tAC level.

In the earlier years (1968 to 1972) landings in subdivision 3Pn represented between $25 \%$ and $38 \%$ of the total catch. This percentage has dropped to below 1\% since 1973.

The purse seines are the gear taking most of the landings, as much as $81 \%$ of the total catch in div. 4 T , and $97 \%$ in subdivision 3Pn, before 1974. The proportion of total landings taken by the offshore fishery has been increasing recently compared to the inshore fishery (Figure 1).

The herring fishery is divided into two main seasons, the spring and the fall, depending on geographical location. In an attempt to study recent trends in the inshore fishery, the whole area between Chaleur Bay and Cape Breton was divided into large areas characterized by similar inshore (gillnet) fishing patterns (Figure 2). The yearly total catch, as well as the proportion from the spring fishery was calculated.

The results (Figures 3, 4, 5, 6 and 7) show a substantial decrease in landings in the Chaleur Bay area (Zone 1), as well as a decline in proportion of catches during the spring fishery, until 1973. Thereafter the relative importance of fishing season fluctuates greatly with years, and the landings are relatively stable despite an apparent increase in fishing effort (Greendale and Powles, 1980). In Zone 2, the landings also declined until 1973, but most of the catch was and is still taken during the spring. Here again an increase in fishing effort was noted between 1971 and 1979 (O'Boyle and Cleary, 1981). In the Pictou and Souris area (Zone 3) the catches from the predominantly fall fishery have increased during the past two years. The 1970 spring fishery appears anomalous. Around Cape Breton Island, Zone 4, the landings also have increased since 1976 following a decline during the period 1967-76 almost all the catches are taken during the spring. In the Magdalen Islands (Zone 5), gillnet catches were not reported until very recently. The reported landings increased significantly in 1979, with a rise in fishing effort (Cleary and worgan, 1981) and then dropped in 1980, (preliminary catch statistics).

Age camposition of the cormercial catch

The catch at age data were taken from Winters pers. comm. The original table presented data for spring and fall spawners separately, but these are here combined (Table 4). The age composition matrix of the total cormercial catch shows that the 1974 and 1977 year-classes have contributed substantially to the fishery in recent years. The proportion of fish age 6 and older has decreased from 91\% in 1969 to $22 \%$ in 1980. The mean age of the catch dropped fram 9 years (1969) to 4 years (1980). This trend towards decreased age persists until 1980, even with the strong 1974 year-class supporting the fishery from 1977 to 1979. Similar trends in proportion of older fish and mean age have been found for purse seiner and trap catches individually, as was an increase in the number of small fish in the catches (Cleary and Trudeau, 1981; Cleary and Worgan, 1981). This situation could possibly reflect changes in purse seiner fleet activity, fish distribution or in year-class strength. However, a shift in population age structure towards younger age classes may also result from heavy fishing pressure, as in the case of the Pacific sardine (Murphy, 1966). Since the seiner fleet has the capacity to search for schools of herring, and since there is no market for fish smaller than 10 inches, it appears probable that no more larger older fish are available to the fishery, forcing the seiners to catch smaller younger fish.

In the cambined (spring and fall spawners) catch-at-age matrix, fish older than 11 years represent up to $38 \%$ of the total catch in numbers in a given year. To perform cohort analysis, numbers of ll+ fish were broken down into numbers at older ages. To do so, the following assumption was made: the ratio of number of fish at age 10/the number of fish $10+$ in 1969 equals the ratio of fish 11/fish 11+ in 1970, and so on. The numbers prorated in this way were used in the cohort analysis.

## Population abundance indices

A number of abundance indices based on catches by research vessels and the camercial fleet were available for the $4 T$ herring stock (Tables 5 and 6; Figures 8 to ll).

In an initial analysis of the purse-seine log books (Figure 8A and Table 5; data from Winters pers. comm.) catch rates (catch/set) remained relatively constant fram 1971 to 1975 with subsequent continual decline till 1980. Later the data were re-analysed (M. Sinclair, pers. camm.), and a different pattern of catch-rates versus time was obtained (Figure 8B). All catch-rate indices fram the southern Gulf, excluding the "Edge fishery" indicated a sharp decline since 1977 (Figures 88 and 9; Table 6).

Catch rates from the "edge" fishery have not shown a parallel decline, although there was a decrease in 1980 (Table 6 and Figure 9). However this fishery does not exploit a stationary herring population, but schools which are migrating fram overwintering to spawning areas. Besides it has been shown (Valdron and Sinclair, pers. corm.) that the seiner fleet has recently changed its area of fishing (since 1977) during the "edge" fishery. Consequently catch-rates from this fishery may not reflect the overall abundance of the stock.

In general, it should be mentioned that purse seiners fish as a fleet; they have searching powers which have improved with time (i.e. introduction of a new sonar in 1976 (McKone pers. corm.)), as well as learning capacity to locate the fish. The validity of seiner catch rates as representative of the fish population abundance has often been discussed, (Powles, 1981; Pope, 1978; Ulltang, 1978) and the facts mentioned above suggest that the catch rates may not reflect the population abundance.

The Southern Gulf groundfish research survey is designed to catch groundfish. Any catch of herring is thus incidental, and catch rates should be accepted with caution. However, there is a general declining trend in herring catch rates since 1970 (Figure 10), giving one same confidence in the results obtained. If the survey was not adequate for herring one would expect that incidental catch of herring would produce fluctuating catch rates with time rather than a series with a trend. In 1980, the research vessel herring abundance index was at its lowest value for since the preceding decade.

Several catch rate series are available from the conmercial gillnet fishery. In general all catch rates series are declining and reach their lowest values in 1979 and 1980 (Table 5 and Figure 11). There has been a gradual increase in gillnet fishing effort during the last ten years (Greendale and Powles, 1980; O'Boyle and Cleary, 1981; Cleary and Worgan, 1981; Messieh, 1981). All catch rates, except for the Magdalen Islands gilinets fishery which uses only anchored gillnets, are biased upward because they do not take into account the searching power and learning capacity of that proportion of the boats using drift gillnets:. Also the catch rate from the Southern Gulf which is measured in catch per successful trip is thought to underestimate the fishing effort (Messieh, 1981). In sum, one would expect a bias in the gillnet catch rate indices such that they may underestimate recent population declines.

The Magdalen Islands trap catch rates are probably the most reliable abundance estimatespresented here since the fishing effort distribution of this fixed gear has been very stable over time: traps have remained in the same emplacements without being moved to concentrate on areas (e.g. spawning beds) where fish are abundant (Cleary and Worgan, 1981). However only spring spawning herring are available to this fishery, and thus the catch rates may not reflect the overall abundance of the stock. The catch rate series shows the abundance of the fish available to be at a historical low in 1980 (Table 5 and Figure 11).

In summary, no abundance index seems to represent accurately the abundance of the whole 4 T herring stock. But despite the biases, most of the catch rate series presented show a decline over the last ten years, and the lowest level in 1980.

Correlations between the various catch rate series are shown in Figure 12. Of all the indices, the autum purse seiner data were highly intercorrelated whatever the units of effort used. Thus, the declining trend of the autumn purse seiner catch rates is independent of the unit of effort used. A high correlation coefficient was also found for the two gillnet catch rates (I and G) from the Southern Gulf. The gill net catch rate (I) and the purse seiner catch rate (C) from the Southern Gulf also correlate well ( $r=0.926$ ), but it should be noticed that both of these indices are thought to the biased upward.

## Mortality rates

An estimate of 0.2 for the instantaneous natural mortality rate (M) was assumed throughout the present analysis. The possibility of fluctuations with time in the natural mortality rate cannot be excluded, but since no accurate calculations of such a change could be done, $M$ was assumed constant.

Total mortality coefficients (Z) were calculated (Table 7) according to the Paloheimo linear formula (1961), using the catch at age from Winters pers. - comm. and the effort values calculated from the following catch rate indices:
a) the research vessel CPUE
b) the Southern Gulf purse seiner CPUE
c) the Southern Gulf gill nets CPUE
d) the Magdalen Islands gillnets CPUE
e) the Magdalen Islands traps CPUE

The average $Z$ values for fully recruited fish were calculated, from 1969 to 1980. The mortality rate between 1979-1980 was always the highest or close to the highest rate since 1969, whatever catch rate was used in the calculation. The average Z for the 1979-1980 period was 1.4.

## Partial recruitment

A partial recruitment vector derived from initial runs of cohort analysis proved to be dame shaped. In their most recent analysis Winters pers:. comm.), with different calculations and assumptions,also came to the conclusion that the partial recruitment vector was dame shaped. However, it was felt that
the historical partial recruitment values were inappropriate, due to the fact that small fish have predominated the catch only in recent years. Since no appropriate values for partial recruitment were found, a new vector was derived by combining the results obtained by Winters pers. comm. and that from initial runs of a cohort analysis:

| Age | 2 | 3 | 4 | 5 | 6 | 7 | 8 | 9 | 10 | 11 |
| :--- | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| PR | .19 | .65 | .9 | 1.0 | .98 | .9 | .85 | .8 | .75 | .7 |

This vector was used to run the cohort analysis.

Yield per recruit

A Thompson and Bell yield per recruit relationship was calculated using the above partial recruitment values, and the weight at age, averaged for the spring and fall spawners (weighted on catch numbers), fram Winters pers. comm.: The $F_{0.1}$ value was 0.331 and $F_{\max }=0.748$.

Cohort analysis

Cohort analysis was run using the above partial recruitment values until an average weighted $F=1.2$ (age 6 to 10 , weighted on population numbers) was found. This value was obtained by subtracting the natural mortality rate of 0.2 from the average total mortality rate ( 1.4 ) calculated earlier from the various catch rate series for 1979-1980. The resulting population number estimates and fishing mortality rates are shown in Table 8. The weighted average $F$ increased from 0.290 in 1969 to 1.203 in 1980.

The population numbers and biomass estimated thus obtained were correlated with:
a) the research vessel catch rate in no/tow (W3 estimator) (Figure 13);
b) the southern gulf gillnet catch rate in t/net-days (Figure 14), and
c) the purse seiners catch rate in $\mathrm{c} / \mathrm{set}$ (Figure 15).

All the coefficients of correlation were above 0.92 .

Herring weights at age for the first quarter of the year (Winters pers. comm.) " were used to calculate a long term series of comparable biomass estimates fram 1969 to 1980 (Table 9). From these estimates, an alarming situation can be seen where the biomass for ages 2 to 11 is estimated to have dropped by 20 fold between 1969 (l 129700 t) and 1980 ( 54600 t ), while mature biomass (age 5 to 11) dropped by more than 40 -fold during the same period.

## Conclusion

The $4 T$ herring stock situation appears to be critical. In spite of high market value for adult herring, TAC levels, although fixed at $50 \%$ of $F_{0}$ have not been reached. Increased inshore effort (Greendale and Powles, 1980; ${ }^{1}$ Cleary and Worgan, 1981; Messieh, 1981; O'Boyle and Cleary, 1981) has not resulted in an appreciable increase of the overall landings. Despite difficulties in interpretation of catch rates, all are at historical lows. The proportion in number of mature fish in the catch dropped more than 4 fold between 1969 and 1980, and the mature biomass is expected to decline further. Furthermore, experimental fishing in the edge fishery area from the 25th to the 30th of April 1981 (A. Sinclair, pers. corm.) yielded no herring. Whatever the reasons for the decline of the stock, it appears from comparison with herring stocks in the eastern Atlantic (Jakobsson, 1980; Dragesund et al. 1980; Saville and Bailey, 1980) that the $4 T$ herring spawning biamass has reached a level where recruitment could be affected.

## ACKNOWLEDGEMENTS

My thanks to Dr Howard Powles, Dr Michael Sinclair and Mr Robert O'Boyle whose help allowed me to accomplish the analysis, and who carefully commented on the manuscript.
