Status and assessment of the Iceland scallop, Chlamys islandica
in the northeastern Gulf of St. Lawrence

Abstract
A stock assessment of northeastern Gulf Iceland scallops is presented. Based on research-vessel surveys, relative age composition in research surveys and commercial catches and fishery performance, it represents the first assessment ever undertaken of this resource. As a result of an interaction of the availability and prices of other exploitable species by a multi-purpose fleet, a pulse fishing strategy for scallops has emerged in this area. In the third year of its second pulse, the fishery has enjoyed relatively stable CPUEs over the period and the assessment points to its continued short to medium-term stability. Long-term management options are discussed.

#### Abstract

Rēsumé Ce qui suit est une évaluation du stock de pétoncles d'Islande du nord-est du golfe du Saint-Laurent. Fondēe sur des relevēs par navire de recherche, la composition relative par âge des prises, tant expérimentales que commerciales, et enfin les rendements de la pêche, cette évaluation est la première à avoir ēté entreprise de cette ressource. A cause d'une interaction entre la disponibilitè et le prix d'autres espèces exploitables par une flottille polyvalente, il s'est dēveloppé dans cette région une stratēgie de pêche "pulsée". Les prises par unité d'effort ont ētē relativement stables dans la troisième année de la seconde phase. Notre évaluation donne à penser qu'elles continueront de l'être à court et moyen terme. Nous examinons les diverses options de gestion à long terme.

## Introduction

The suspension-feeding Iceland scallop, Chlamys islandica, has its main distribution within the subarctic transitional zone - subarctic or northerly boreal (Ekman 1953). In Newfoundland, local populations are normally found in waters deeper than 30 fms ( 55 m ), usually on hard bottom with variable substrate composition consisting largely of sand, gravel, shell fragments and stones. Being a filter feeder, the species is most abundant in areas where there are strong currents as in the Strait of Belle Isle in the northeastern Gulf of St. Lawrence. Other areas where Iceland scallops are found in quantity include St. Pierre Bank (3Ps) and along the Labrador coast, particularly off Nain and West St. Modeste where a small fishery is underway. Although sizeable beds of Icelandics occur on St. Pierre Bank, no commercial effort is expended here. Of the three areas, beds located in the northeastern Gulf are the most easily accessed, frequently occurring within 2 mi of the coast.

Although the day fishery in the Gulf for Iceland scallops began in 1969 when 224 MT (round) was landed, studies on the distribution and population dynamics of Chlamys did not commence until 1973. Landings receded slightly to 173 and 151 MT in the two succeeding years. In 1972 and 1973, however, landings from the hand-shucked fishery increased sharply, concomittant with a changeover to 2.5 from 3.0 in. rings, to 2342 and 1975 MT, respectively (TabTe 1). Towards the latter part of the 1973 season, scallop prices fell. Herring and cod were abundant and a new year-class recruited to make shrimping more lucrative. As effort expended on labor intensive scalloping depended on an interaction of the availability and prices of several other species then available to the mobile multi-purpose vessels, the percentage of vessels fishing scallops thus decreased. A combination of severe ice conditions and poor prices in 1974 resulted in a further diversion of effort into other species and decline in total landings (Table 1). There was no active fishery during the 1975-78 period. Unfortunately no systematic annual sampling of scallops was carried out during the first fishing pulse in the northeastern Gulf. Consequently, the data base on past stock characteristics is fragmented and at best inconclusive.

Scallop fishing resumed in 1979 when 406 MT were taken. Landings increased to 1022 and 1380 MT in 1980 and 1981 respectively, with a combined landed value exceeding 2 M dollars. The recent resurgence of this fishery has renewed our interest in this stock, particularly from the point of carrying out suitable assessments and, if needed, developing appropriate management strategies for the fishery. The second pulse has continued every summer for the past three consecutive years. An intensive commercial sampling program was initiated in 1980. In addition a two-dimensional systematic survey was conducted in 1980 to enumerate population numbers, and repeated in 1981. The assessment presented here is based largely on these surveys and on the fishery characteristics from the second pulse of exploitation.

The fishery remains unregulated with the exception of it being designated as a limited entry fishery for boats in excess of $40 \mathrm{ft}(1980-81)$ and 35 ft (1982). Individuals holding licences for vessels over 35 ft who have not utilized the licences in 1980 or 1981 will not be-eligible for renewal in 1982.

## Materials and Methods

On the basis of individual interviews with active scallop fishermen and local DFO personnel, an area about 114 sq nautical miles was delineated as the principal fishing area. Sample surveys based on a systematic lattice design were carried out in this core area to explore and determine the spatial structure of the scallop population and to assess the suitability of this type of sampling design for resource management purposes (Naidu and Smith 1981). The procedures involved in setting up a systematic lattice design are described in Smith and Naidu (1981). Eleven latitudinal transects, each spaced one nautical mile apart, were run in the target area (Fig. 1). Stations were assigned at 0.5 mile intervals along these lines. One hundred and three stations were occupied in 1980 (Fig. 1, closed circles) but operational constraints reduced the coverage to 59 in 1981 (Fig. 1, open circles). Fishing stations in waters less than 30 fms ( 55 m ) were deleted from the lattice as no commercial effort was expended at these depths.

Both surveys were conducted during July-August with the 18.6 m government research vessel, the M.V. MARINUS. All tows were made with a gang of four toothless Digby buckets mounted on a single tow bar. Dredges were equipped with 2.5 in ( 64 mm ) rings and carried a 1.5 in ( 38 mm ) polypropylene mesh liner to increase retention of smaller scallops. The liner was inspected frequently and repaired or replaced as necessary. Each tow attempted to cover exactly 0.25 nautical mile with a $3: 1$ wire scope.

Dredges were hauled up at the end of each tow and the catch was "bushelled" into baskets and weighed to the nearest pound. Individual live shell-height frequencies were recorded (to the nearest mm ) on either the whole catch, or a weighed random subsample, depending on the amount caught. In the few (5) instances when subsamples were employed in 1981, counts were made of all animals not measured. All cluckers were counted and measured, again to the nearest mm. Random shell samples from throughout the survey grid were retained for subsequent age determinations. Notes were kept on the volumes and types of substrates encountered in the area fished. Biological sampling for individual adductor muscle weights was carried out at on-shore locations with fresh scallops.

During the 1980 scallop survey 10 scallops were tagged and released at each of the 108 fishing stations, ensuring that the tagged population of 1,080 scallops was evenly distributed over the fishing area. Tagging was accomplished by drilling a small hole through the one unequal wing protrusion and a numbered yellow Peterson disc manually secured in place with a Type $304,0.4 \mathrm{~mm}$ diameter stainless steel wire (Fig. 2). Excess wire was trimmed to the twist and the latter tucked neatly over the disc.

In 1973, Mr. M.C. Mercer, scientist then in charge of scallop investigations, had conducted separate gear selectivity trials for Iceland scallops in the northeastern Gulf of St. Lawrence using Digby dredges of similar construction equipped with 2.5 in . and 3.0 in . rings. Dredge covers employed on alternate dredges consisted of 1.5 in . mesh courlene with a. 2.0 in mesh double-braided courlene jacket for chafer. Both cover and chafer were attached to dredges as a "bag-like" affair, extending beyond the length of the dredges and terminating with a cod-end which facilitated dumping and separation of the catch. The unpublished data from these investiations have been analyzed for use in this assessment.

Information on scallop landed, either shucked meats or in the shell, fishing areas and size composition of catches was obtained from port samples, fishing logs, commercial sampling statistics and interviews with fishermen.

## Results

## Resource surveys

Estimates of exploitable scallop biomass in the northeastern Gulf of St. Lawrence based on resource surveys using a systematic lattice sampling scheme were given by Naidu and Smith (1982). The results are summarized in Table 2.

Assuming a Gaussion distribution for sample means we note that the $95 \%$ confidence intervals for estimated mean numbers of scallops for the two years do not quite overlap, although the confidence intervals for the estimated mean weight do. Minimum biomass in 1980 and 1981 is estimated at 2,465 and 3,000 MT respectively (Table 2). Coefficients of variation ( $\mathrm{SE} / \mathrm{Y}_{\text {st }}$ ) range from 7.6 to $5.4 \%$ - a level of precision seldom attained in resource surveys of this sort. Overall average density of scallops in the area surveyed was $6-8 / 10 \mathrm{~m}^{2}$. Given the distributional assumptions this points to little change in abundance in the two years.

Tag returns have been too sparse and infrequent (3 and 9 returns in 1980 and 1981 respectively) to be of much use at this time. Of these only six were returned (all in 1981) with the shell intact. No appreciable growth was evident.

Broadly, the bottom may be characteristized by two general substrate types: a hard, rocky southern area (transects 1 to 7) and a smoother, softer bottom in the north (Transects 8-11) consisting mainly of coarse sand and shell fragments.

Growth
Rings on the left (upper) valve have been used in this study to determine ages and in back calculations (Fig. 2). Not all animals are readily aged from shells. Epifaunal organisms quite commonly found on the surface of the upper valve often conceal all clues, effectively precluding age determinations (Fig. 3). Shells that are likely to be aged are cleaned in a weak solution of HCL and brushed radially from the umbo outwards to the shell periphery. Thus prepared, approximately $30-40 \%$ of shells in a sample may be aged successfully by mere inspection. An even smaller percentage was used in back measurements. Expressing growth as a function of shell height in this species is further constrained by a phenomenon in some animals whereby growth beyond a certain size (variable) does not manifest itself through further increases in linear dimension, but becomes flush-laminal (Fig. 4). As many as four layers have been defected in some specimens, annual growth in these presumably expressing itself through the deposition of a distinct and separate lamina. With time the shell margin becomes thick. Infrequently the most recent lamina may resume feeble growth along the dorso-ventral axis, but the deposited shell appears to be delicate and easily damaged.

Von Bertalanffy growth parameters for northeastern Gulf Icelandics were calculated (Abramson 1963) from back measurements employing 284 scallops (Table 3, Fig. 5). Estimates of similar parameters for scallops from St. Pierre Bank are given for comparison (Table 4). Although depth had a profound effect on growth rate ( $K$ ) and Loo values for scallops from St. Pierre Bank, no attempt is made in this assessment to factor depth into these parameters. Indeed an examination of mean shell heights within the three most important depth strata in the area, viz. $30-39,40-49$ and $50-59$ fms showed little variation (79.03, 79.07 and 79.46 mm respectively). Comparisons of the means from the two extreme depth ranges indicated no significant statistical difference ( $P<0.05$ ). There was a tendency, however, for scallops to be somewhat larger northwards, particularly beyond transect No. 8 (Table 5). These differences are probably related to factors other than depth and are ignored in this first assessment.

In order to at least partly address the problems of shell curvature (Naidu 1975) and shell lamination, an age-length key was constructed using the complete shell height-at ring formation data ( $N=2670$ ) and used to generate scallop ages at given shell heights rather than using mean shell-height at age (Caddy and Jamieson 1977, Jamieson et al. 1980).

## Shell height-meat weight relationship

Data from earlier resource surveys were combined with more current data obtained monthly through the 1981 fishing season to compute the relationship between $W=c L^{\prime}$, where $W=$ weight of adductor muscle, $c$ and $b$ are constants. These are derived from the least squares regression of the logarithmic transformation $y=a+b x$ where $y=\log _{e} W, a=\log _{e} c$ and $x=\log _{e} L$ (length in mm and weight in g, Table 6)

$$
\begin{equation*}
\log _{e} y=2.85 \log _{e} x-4.44 \tag{Fig.6}
\end{equation*}
$$

As manual shucking habits vary amongst fishermen and are frequently dictated by buyers, both the large smooth (quick) and smaller striated (catch) fractions were included in the computation of parameters. The relationship between muscle-on (both components of adductor muscle) and muscle-off (adductor muscle less catch fraction) was found to be linear ( $r^{2}=0.99$, Fig. 7), with no discernable correlation ( $r^{2}=0.02$ ) of the ratio of their weights with scallop size (Fig. 8). This facilitated conversions of landings from muscle-off to muscle-on and vice versa. But an analysis of covariance of the logarithmic transformations of muscle weight on shell height pointed to significant seasonal differences in the adjusted means ( $P<0.01$ ) for plant samples for the period April to August (Table 7). This required the use of different factors for conversions of meat to round weights.

The effect of depth on meat yield, if any, has not been investigated.

## Gear SeTectivity

Selectivity analyses (Tables 8 and 9) are preliminary. Scallop selectivity by commercial gear was approximated by comparing lined catch data (i.e. number actually entering gear) with the unlined catch data. Over the vulnerable size range, the 2.5 in unlined dredges caught $79 \%$ as many scallops as the lined dredges. The $50 \%$ retention shell heights for the $2.5 \mathrm{in}(64 \mathrm{~mm})$ and 3.0 in
( 76 mm ) mesh were 70 mm and 91 mm corresponding to mean retention ages of 8 and 13 respectively (Fig. 9). The extremely poor retention by the larger mesh was no doubt responsible for the somewhat rapid changeover to 2.5 in rings during the third year of the fishery. Lined dredges ( 2.5 in rings) were nearly five times (4.75) as efficient in retaining pre-recruit scallops ( $<70 \mathrm{~mm}$ ) as the unlined. For scallops $>70 \mathrm{~mm}$, the unlined commercial was only marginally more retention efficient ( $8 \%, \bar{N}=637$ vs 592 ) but resulted in an increased total yield of $10 \%$ by weight ( 6694 vs 6115 g , (Table 9). Actual retention rates for the commercial gear would be somewhat higher as fishermen usually tow to saturation. Retention ratios greater than 1.0 were observed in $77-100 \mathrm{~mm}$ range. Values for selectivity ogives exhibited a downward trend beyond the size where $100 \%$ retention was attained. A similar phenomenon was reported by Serchuk and Smolowitz (1980) for a 2.44 m research scallop dredge for the capture of Placopecten magellanicus. Research and commercial shell-height frequencies are compared in Fig. 11 .

First fully vulnerable age group to commercial gear is 8 yrs (Fig. 10). It is apparent as well that the better research-gear estimate of to-be recruited year-class strength is based on 7 year olds since 6 -ring scallops ( 61 mm ) are only fractionally retained by the gear.

Because of the type of bottom commonly encountered in the northern Gulf fishery, the configuration of the rings itself is subject to change with fishing (Table 10). This is usually manifested by elongation of rings in the direction of tow and sometimes oblique to it. This departure from the near-circular configuration is problematic from the point of gear selectivity. As meshes become clogged with tow distance, most escapement must take place during the first few minutes of a tow. Typically, the longer the tow, the more tenuous becomes the relationship between escapement and mesh size, especially when the total capacity (volume) of each individual dredge is considered. Some, if not most escapement beyond a critical tow distance, must occur by accident (gear behavior on bottom) rather than by gear selection per se. As buckets become filled, the induced hydrodynamics of the water mass immediately preceding the moving dredge must also change, 'preselecting' sizes and weights of objects (including scallops) that enter it. Larger, heavier scallops in the path of such a dredge are more likely to gain entrance than smaller ones. This may explain the higher efficiency of commercial gear in retaining greater numbers of commercial-sized scallops. The few prerecruits that do gain entrance, of course, have a greater probability of escapement. This preselection is particularly critical for lined gear as it tends to fill up more rapidly than the unlined. For the tow duration used in our research surveys, however, the problem is not critical.

It should be noted that the $50 \%$ selection point for the dredge now in use in the commercial fishery ( 70 mm ) is greater than the theoretical diameter of dredge rings ( 64 mm ) which are variously linked with washers (usually two). This indicates that both the stretched configuration of the mesh (Table 10) and the inter-ring spaces feature prominently in selection.

No data are available for efficiency of capture of this species with Digby buckets. A maximum efficiency of $20 \%$ is assumed in this study.

## Commercial Age Frequencies

Monthly comparisons of scallop age frequency landed in 1980 and 1981 (Tables 11, 12) show that 9 and 10 year olds represent some $45 \%$ of all scallops landed. This catch composition was maintained through both seasons. The numerical superiority of these age groups in two successive years is suggestive of good recruitment and reflects fleet-mobility. Nearly $80 \%$ of all scallops landed in the two years combined consisted of age groups 8 to 11 (Fig. 10). While older scallops are still represented in the catches it is evident that much of the harvested biomass is from recruitment during and immediately following the first fishing pulse. The $15+$ age group in both research and commercial catch samples consists of a mixture of year-classes and therefore contains more individuals than the group immediately preceding it.

## Research Age Frequencies

Apart from the better representation of pre-recruit age groups ( $\leq 7$ ), research vessel age frequencies are not unlike those obtained from commercial catches, but with ages 8 and 9 being most abundant (Fig. 10). Relative abundance of prerecruits to recruits suggests that recruitment has not been subject to wild fluctuations as has often been reported for the giant or sea scallop (Dickie 1955). Prerecruits are moderately (Transects 2, 4, 7, 8, 10 and 11) to well represented (Transects 1, 3, 5, 6 and 9) in the survey area (Tables 13, 14 and 15), pointing to regular recruitment since production peak in 1972-73.

## Natural Mortality

Natural mortality was computed directly from the percent occurrence of cluckers (persistent paired valves still attached at the hinge line) that died from natural causes according to the equation:

$$
a=1-e^{-\left(\frac{c}{t}\right)\left(\frac{1}{L}\right)^{365}}
$$

where $a$ is the natural mortality rate, $c$ is the number of cluckers in a sample, $L$ is the number of live scallops in the same sample, and $t$ is the average time in days required for the valves of cluckers to separate naturally. Time required for natural clucker disarticulation ( 210.8 days) is that determined experimentally by Mercer (1974). The age-length key developed in this study was used to determine clucker ages at given shell heights and age-specific natural mortality rates calculated. These were computed separately for the two years (Table 16). Except for the $15+$ age group, the rates so calculated were substantially lower during the second year of the survey. An analysis of covariance of the logarithmic transformations of $M$ on age (Fig. 12) pointed to no significant differences in slopes ( $P<0.05$ ) but elevations were different ( $P<0.01$ ). The significant difference in the observed rates is probably an indication of the extent of indirect fishing mortality associated with repetitive tows in areas where significant fisheries occur for the mollusc. During the current pulse there has been a tendency for the fleets to move south particularly during 1981. In reality boats have moved away from areas of heavy exploitation into new, virgin grounds. The observed mean difference in the average mortality rates between the two years may be considered to be a first estimate of indirect fishing mortality, albeit provisional.

Fishery effort and landings
Annual landings (Table 17) have shown wide fluctuations. There is very little detailed information on fishery performance from the $1969-73$ period. Mean annual catch from the second pulse (1979-81) is slightly above the average reported for the first ( 936 vs .845 MT ). Since nearly all the catch is sold to registered buyers, data on total landings by month for 1974, 1979, 1980 and 1981 are considered quite accurate (Tables 19-22). Effort levels have been quite variable (Tables 23-26) and appear to have caused the reported fluctuations in monthly and annual landings. There appears to be little doubt that the initial surge in landings in 1972 and 1973 was related to the changeover from 3.0 to more retention-efficient 2.5 in rings in a developing fishery.

Little is known of total fleet behavior during the 1969-73 period. Anecdotal information suggests that some boats operated in a fairly restricted general area whereas others moved as they fished out local concentrations. If this is indeed true, it is likely that boats still using the 3 in mesh were the ones that had to move about locating and removing concentrations of accumulated older ( $>90 \mathrm{~mm}$ ) scallops. Substantial quantities of scallops in the $70-90 \mathrm{~mm}$ range that would have escaped the 3 in gear would have been still available for capture by boats using dredges equipped with 2.5 in rings.

Voluntary logs were introduced into the fishery in 1980 (Fig. 13). To improve completion rate and ensure continued cooperation in completing logs, catch summaries were sent to individual fishermen. Only data relevant to the boat were provided. This feedback has been quite positive. Quality of catch and effort data has improved. In 1980, for example, because of variable reporting, only number of days fished could be used for effort. In 1981, however, information on numbers of hours fished is also available. More precise locational information is also being made available in contrast to 1980, where areas fished would be recorded simply as $4 \mathrm{mi} N W$ of Anchor Point, etc.

No attempt has been made to either standardize vessels by size (42 to 55 ft range) or by gear ( 4 to 6 Digby buckets, the majority, $75 \%$, using 5 ). The use of numbers of days fished is the only effort measure available and is fraught with difficulties. Neither the length of day nor the quality of the expended effort remain constant. In an attempt to remove some of these variables, we examined behavior of both the total fleet (Tables 27-30) and the core fleet (Tables 31-35), the latter consisting only of the more experienced vessels that enter the fishery early in spring and remain scalloping through the fall. Contributions to total catch notwithstanding, the core fleet should give a better idea of how CPUE has changed, if any, between and within seasons. Using such effort data as are available it is apparent that total effort by the core fleet increased by a factor of 1.9 and 1.2 in 1980 and 1981 resulting in 2.5 and 1.4 -fold increases in landings (Table 17). Although catches have kept pace with effort, CPUEs for the core fleet increased by a factor of 1.3 in 1980 and suffered a $10 \%$ drop in 1981, but remained slightly above the 3 yr average of 2564 lb (round)/day. Monthly CPUE within the fishing season shows a decreasing pattern. From a usually sluggish start (first month), monthly catch/boat day for the fleet, for nearly every year for which data are available, increases to June/July, thereafter decreasing variously to record lows for the year. While weather and length of day may be factors at the start and termination
of fishing seasons, it is difficult to explain the decreasing trend during the June-September period. Areas fished by the fleet in 1981 (Fig. 14, Table 36) and catch/tow and catch/hr of two boats with excellent logs (Table 37) were examined in detail. It is clear that the fleet operates farther from home ports during the long summer days and tends to shift to more readily accessed, even if less productive beds, later in the season (Table 38). In 1981, fishing was mostly directed in Sectors B, C and D (Fig. 14). Within these, approximately $66 \%$ of effort was in a 5 mi zone extending 10 to $15 \mathrm{mi} W$ to NNW of Anchor Point. As is noted later, many boats operating out of Black Duck Cove shift from landing scallops in-the-shell to shucked meats around August. The additional work involved with manual shucking on board may well affect total quantity of scallops caught. There is very little culling at sea. Neither the mean shell height nor the mean meat count/lb between the two years for which detailed data are available (Table 18) show a pattern to suggest the exploitation of smaller scallops. Dispersal in Placopecten has been suggested as a factor contributing to reduced seasonal catchability (Jamieson 1980). A similar explanation in Chlamys would be somewhat less plausible on account of its reduced mobility, particularly of the commercial-sized animals. While it is difficult to isolate the cause(s) for the observed decreases in monthly CPUE, we must take a conservative approach and assume that localized stock depletion related to fishing is taking place, resulting in reduced availability and fleet movements.

The scallop fishery in this area has a very complex socio-economic base. In 1980 scallop prices on the island-side of the Strait of Belle Isle were stable ( $\$ 3.25$ meats $/ 23 \$$ round at Fisheries Products in Black Duck Cove, $\$ 3.30$ at $T$. J. Hardy Ltd. in Anchor Point) from the beginning of the fishing season (April) until the FPU strike in mid-July, during which both plants were closed. At this time Walter Biggins Ltd. of Port Saunders set up a freezer truck at Anchor Point and became the only purchaser of scallops (at \$3.40). With the end of the strike in late August, both plants reopened. During the following two weeks all three buyers started raising prices. By the first week of September, T. J. Hardy Ltd. had ceased buying scallops, and prices had stabilized with the other buyers ( $\$ 4.30 / 30 \$$ at Fisheries Products, $\$ 4.30$ at Walter Biggins Ltd.). In early October, Biggins again raised his price, so that at the end of the season fishermen were receiving $\$ 4.50$ from Walter Biggins Ltd. and $\$ 4.30 / 30 \$$ from Fisheries Products Ltd.

Black Duck Cove fishermen generally patronize their community fish plant (Fisheries Products Ltd.), landing mostly shell-on until late August when they begin shucking the animals themselves. This strategy allows members of the family to be gainfully employed as shuckers at the fish plant and facilitate the collection of UIC benefits during the ensuing winter. As soon as these benefits are secured fishermen begin to shuck scallops to improve the profit margin and boost incomes (assuming 100 lb round yields $11 \mathrm{1b}$ meat, at a price of $\$ 4.30 / 30 \$ 100 \mathrm{lb}$ round $=\$ 30.00$, while 11 lb meat $=\$ 47.30$ ).

Anchor Point fishermen land some scallops shell-on at Black Duck Cove, but by and large land meats only. Prior to the strike they landed meats at T. J. Hardy Ltd. in Anchor Point, switching to Walter Biggins Ltd. for the remainder of the season.

Labrador fishermen landed only meats, selling. to Northern Fisheries Ltd. of Lanse au Loup (at $\$ 3.30$ ) for most of the season. In mid October, Walter Biggins

Ltd. arrived and started paying $\$ 4.40$; this price held until the end of the season (mid-November). With the arrival of Walter Biggins Ltd., Northern Fisheries Ltd. ceased purchasing scallops.

During 1981 prices paid to island-based fishermen started high, and gradually declined over the course of the season. All three buyers from the previous years were again buying scallops at the start of the 1981 season ( $\$ 4.70 / 354$ at Fisheries Products Ltd. in Black Duck Cove, $\$ 4.75$ at T. J. Hardy Ltd. and $\$ 4.70$ at Walter Biggins Ltd., both in Anchor Point). By early May T. J. Hardy had discontinued buying and the others had started dropping their prices, so that by early June prices stood at $\$ 3.90 / 284$ at Fisheries Products Ltd. and $\$ 4.05$ at Walter Biggins Ltd. Following further reductions during July and August, prices stabilized in mid-August ( $\$ 3.35$ at Fisheries Products Ltd. and $\$ 3.40$ at Walter Biggins Ltd.) and these remained in effect for the rest of the season.

As in 1980, Black Duck Cove fishermen sold their catch primarily to Fisheries Products Ltd. Again the catch was landed mainly shell-on until August, at which time they switched to landing meats. Starting in August, two boats began regularly selling to Walter Biggins Ltd. as he was buying meats with the catch muscle attached without price differential.

Most Anchor Point fishermen started selling to T. J. Hardy Ltd. When T. J. Hardy stopped buying in May, they sold their catch to Walter Biggins Ltd for the remainder of the season.

The Labrador season started in May, with Walter Biggins Ltd. being the only buyer ( $\$ 4.10$ ). In late May, Southern Labrador Fisheries Ltd. of Forteau started operation, buying both shell-on and meats ( $\$ 4.00 / 28 \$$ ). Walter Biggins Ltd. stopped buying at this point because the fishermen started selling shell-on in an effort to provide employment for shuckers at the plant. For the remainder of the season Southern Labrador Fisheries Ltd. was the only buyer. Over the season the price for meats dropped to $\$ 3.75$ while the price for shell-on rose to 304 .

Labrador fishermen landed mainly shell-on for the whole season. "In August the island fishermen started sending their meats to Southern Labrador Fisheries Ltd. to take advantage of the higher price. But the Labrador plant was mainly interested in buying shell-on in order to provide employment so they lowered the price for meats while at the same time raising the price for shell-on scallops. This had the effect of discouraging the island fishermen from selling meats there, while at the same time ensuring that Labrador fishermen landed their scallops shell-on.

## Yield per recruit considerations

Adductor muscle weights at age were used to determine yield ( kg ) per 10,000 recruits for varying levels of $F$ as in Thompson and Bell (1934). A family of yield curves were generated for $t_{p}$ ' between 6-12 yrs and varying rates of natural mortality (Table 16). All ${ }^{\text {P }}$ curves were essentially flat-topped and showed asymtotic yields as $F \rightarrow \infty$ (Fig. 15). Mean age at first capture ( $t_{p}{ }^{\prime}$ ) appears to be between 6 and 7 yrs , but it is apparent that scallops are
not fully recruited until 8 . Knife-edge recruitment has been assumed to occur at this age.

Estimates of annual $Z$ for the $1980-81$ period (Table 39) show $F$ to increase with age with a weighted mean at $Z=0.74$, corresponding to an $F$ of 0.59 . This increase is probably related to the observed increase in natural mortality (M) with age. Senescence alone cannot explain the high M values associated, particularly with the fully recruited commercial sizes ( $\geq 8 \mathrm{yrs}$ ). It.is suggested that fishing itself contributes substantially $\overline{\text { to }}$ the higher total mortalities with age. Allowing for the indirect fishing mortality earlier estimated at 0.067, we approximate $F$ at 0.52 . Predicted yield per 10,000 recruits at this level of $F$ is between 76 and $85 \mathrm{~kg}(\bar{x}=81 \mathrm{~kg})$ close to the $F_{0.1}$ yield. Observed performance in the fishery in terms of yield is higher at $99 \mathrm{~kg} / 10,000$ recruits. This corresponds to a predicted meat count (muscle-on) of 55 per lb ( $121 / \mathrm{kg}$ ) versus a realized yield of 46 meats $/ 1 \mathrm{~b}$ ( $100 / \mathrm{kg}$; Table 18) ; i.e. present performance is greater than would be expected under equilibrium conditions. Numerical values notwithstanding, this is suggestive perhaps of the yet continued availability in this fishery of pockets of virgin biomass for first exploitation.

The yield equation is an explicit long-term representation of a fishery between yield and fishing activity and assumes equilibrium conditions. In fact changes in both gear selectivity and fishing effort have occurred and it would take several years of continued exploitation before steady-state conditions are attained, if indeed the fishery continues on a sustained rather than periodic basis. Yield per recruit considerations must therefore be viewed with caution in assessing the status of this non-stabilized fishery.

## Discussion

The problems of enumerating populations from research-vessel surveys is not new in fisheries literature. In this study two major considerations in biomass estimation have been knowing the efficiency of the sampling gear and exact distribution of the target species. An attempt has been made to take the latter into consideration by limiting our surveys to the area delineated by the fishery itself. When surveys must cover large areas, stratified random designs are used with some arbitrary ranges of depths usually used as the stratifying variable. The presence of autocorrelation (the observation that samples taken close together in space are more likely to be similar than samples taken farther apart) in these types of surveys is usually ignored due to temporal changes affecting the spatial patterns in the case of mobile species and/or because samples are spaced at sufficiently large distances to reduce the effect of autocorrelation on variance estimates. For small-scale surveys of sedentary species where samples may be drawn very close, the degree of autocorrelation can have an effect. The sampling scheme used in our surveys provided the optimum design with respect to minimum variance (Smith and Naidu 1981). The problem of gear efficiency and selectivity is somewhat problematical, particularly in relation to the demonstrated instability associated with mesh size. Performance of gear is influenced by many variables including scope, slope, relative velocity of gear with current, nature of substrate, and type of bottom. It is likely that relative efficiency in the more northerly transects (Nos. 8 to 11) was higher than in the rougher bottom farther south. Until these factors are taken into consideration all estimates of biomass should be considered measures of relative rather than absolute biomass. Little is known on the locomotory abilities in Chlamys. For comparable sizes it is probably a less efficient swimmer than Placopecten.

The age matrix developed for scallop ages is suggested to be more realistic than conversions from mean-size-at-age data using von Bertalanffy growth parameters. The method used in this paper at least partly addresses the prablem of laminating shells and, more importantly, factors variance in size-at-age, thus minimizing errors in conversion from size to age.

While the assessment is based on an admittedly short data series, it is apparent that in spite of increased landings in the last three years, predicted by one of us (Anon. 1981), and the marginal drop in overall CPUE in 1981, the likelihood of a major stock decline is minimal. While some seasonal decrease in CPUEs is evident, overall CPUEs have been maintained. Resource surveys in both 1980 and 1981 indicate fairly stable levels of recruitment. Because of the relatively high abundance of prerecruits, particularly of 6 and 7 year olds, whose abundance is known to be underestimated by the sampling gear, sufficient biomass within the area presently fished is available to provide continued stability to the landings over the next few years. Nine- and ten-year-olds will continue to be the mainstay of the fishery for yet another year or two. The availability farther south of yet-to-be exploited patches of accumulated virgin or recovered biomass would tend to add additional stability to the fishery. Fishery performance is likely to depend on total effort expended in relation to the abundance and availability of other exploitable species as and when they become available. Some effort diversion into fin-fish species, particularly cod, may be occurring this year. A decrease in landings could therefore result. On the other hand the failure of the Georges Bank fishery may prove providential to scallop fishermen here and elsewhere as scallop prices will tend to be quite firm through 1982. The present limited-entry designation in this fishery for boats exceeding 35 ft ( 11 m ) with a provision for its utility would appear to provide the necessary check on explosive and sudden surges in effort as was evident during the first pulse. Additional restrictions might prove overly restrictive at this time. A management strategy based on effort regulation is probably more appropriate in an expanding fishery than catch limitations, particularly in that variations in production cannot be narrowly predicted.

As there is very little culling at sea the introduction of a meat count will have very little effect unless regulation mesh size is simultaneously increased. In any case this could be complicated by a pattern now well established in the fishery whereby boats are landing both meats and scallops in the shell, a strategy with immense socio-economic ramifications.

The following management options are recommended:

1. Efforts should be made to establish a Northern Gulf Scallop Advisory Committee to optimize management of the fishery.
2. The pursuit of a multi-species stock management strategy should be examined.
3. Pulse fishing is a form of voluntary closure that should not be discouraged, but perhaps formalized.
4. Promote measures to encourage fuller utilization of the Iceland scallop. A meat/roe fishery could result in a $50 \%$ increase in yield with only a marginal increase in effort. A somewhat persuasive argument may be advanced on this option by yirtue of the fact-of it being a day fishery.
5. Protection of prerecruits until they reach harvestable sizes and reducing loss through indirect fishing mortality should be legitimate management concerns.
6. With a prototype shucking machine now ready for field testing its introduction into the fishery appears imminent. It is recommended that such introductions be delayed until their impact on the total fishery is fully assessed.

| F | - | - | - | - | - | - | - | 0 |
| G | - | - | - | - | - | - | - | 0 |

Table 39. Estimates of $Z$ and $F$ for $1980 / 81$ in the northeastern Gulf of St. Lawrence using the equation $\left.\left.Z=-7 n\left[c_{2} / f_{2}\right] /\right] c_{1} / f_{1}\right]$ and varying $M$ (see Table 16). $c_{1}, c_{2}=$ catch in numbers in year I and year II and $f_{1}, f_{2}=$ effort (boat days) in year I and II.

| Age | $Z$ | $M$ | $F$ |
| :--- | :---: | :---: | :---: |
| $9-10$ | 0.463 | 0.125 | 0.338 |
| $10-11$ | 0.731 | 0.159 | 0.572 |
| $11-12$ | 0.964 | 0.186 | 0.778 |
| $12-13$ | 1.290 | 0.234 | 1.056 |
| $13-14$ | 1.684 | 0.253 | 1.431 |
| $Z_{(9-13)} 0.7417$ | $\bar{M}_{(9-13)}=0.156$ |  |  |

Fig. 1. Distribution of fishing stations in 1980 and 1981 in the northeastern Gulf of St. Lawrence.

Fig. 2. Growth rings and a tagged Iceland scallop. Scallop on left is 88 mm .

Fig. 3. Typical epifaunal growth on the left valve of Chlamys (x $1 / 3$ ).

Fig. 4. Laminated shell edge in Chlamys (x 2).

Fig. 5. Von Bertalanffy growth curve for northeastern Gulf Iceland scallops. Sample means shown.

Fig. 6. Regression of adductor muscle weight ( g ) on shell height ( mm ) ( $r^{2}=0.96$ ) for northeastern Gulf scallops.

Fig. 7. Relationship between-'muscle-on' to 'muscle-off' weights in Chlamys. (muscle-on $=$ both components of adductor muscle; muscle-off = adductor muscle less small catch fraction).

Fig. 8. Scatter diagram: Ratio of quick to catch fractions with scallop size.

Fig. 9. Selectivity ogives for Digby buckets equipped with (A) 3.0 in ( 76 mm ), and (B) 2.5 in ( 64 mm ) rings: solid lines for covered gear; broken lines for commercial gear. All curves drawn by eye.

Fig. 10. Commercial and research age frequencies.

Fig. 11. Commercial and research shell-height frequency distributions
(A) 1980, (B) 1981.

Fig. 12. Relationship between annual mortality and age in scallop beds subject to different levels of fishing.

SCALLOP LOG
(use a new sheet each fishing day)
DATE $\qquad$ BOAT $\qquad$
TOTAL NUMBER OF TOWS $\qquad$
TIME OF FIRST TOW $\qquad$ TIME OF LAST TOW $\qquad$
amount caught: shell on $\qquad$ (estimate these if you do not MEAT ONLY $\qquad$ have actual weigh-in figure)
ACTUAL HOURS SPENT FISHING: $\begin{array}{lllllllll}2 & 4 & 6 & 8 & 10 & 12 & 14 & 16\end{array}$
(circle number of hours)
TIME LOST FOR ENGINE TROUBLE OR REPAIRS $\begin{array}{llllll}2 & 4 & 6 & 8 & 10\end{array}$
(circle number of hours)
PLEASE MARK AN "x" IN AREAS FISHED THIS DAY:

Fig. 13. Scallop log used in 1981 (reduced in size).

Fig. 14. Distribution of fishing effort in 1981 and aereal expansion in the fishery. Percentage indicate effort in each of the three sectors ( $B, C$, and $D$ ). Cross-hatched area indicates where approximately $66 \%$ of effort was expended.

Fig. 15. Yield curves for northeastern Gulf Iceland scallops $F_{0.1}$ values represented by open circles, $x$ represent $F_{\text {max }}$.
