Stock Assessment of Tikkoatokak Bay Arctic Charr

by<br>J. Brian Dempson<br>Department of Fisheries and Oceans<br>Research and Resource Services<br>P. 0. Box 5667<br>St. John's, Newfoundland<br>AIC 5X1

#### Abstract

Catches of Arctic charr in Tikkoatokak Bay increased steadily from 1974 to 1978 when 55 t were removed. Since 1979 this stock has been under quota management with a TAC of 28.5 t in 1981. Stock projections for 1982 were calculated from cohort analyses although only five years of data were available. Population numbers generated from terminal fishing mortalities of 0.4-0.6 indicated an $\mathrm{F}_{0} .1$ yield in 1982 between 21.3 and 34.9 t .

## Résumé

Les prises d'omble chevalier ont augmenté régulièrement dans la baie Tikkoatokak de 1974 à 1978, année où 1'on captura 55 t. Depuis 1979, ce stock est soumis à un contingent, le TPA de 1981 ayant été fixé à $28,5 \mathrm{t}$. Bien que les données disponibles ne couvrent que 5 ans, nous avons fait des projections pour 1982 à l'aide d'analyses de cohortes. Les effectifs de population déduits d'une mortalité par pêche de dernière année de 0,4-0,6 indiquent un rendement à Fo, 1 de 21,3 à $34,9 t$ en 1982 .

## Introduction

Catch statistics for the northern Labrador Arctic charr fishery have been available from individual fishing areas since 1974. The largest catches of charr from 1975 to 1980 were from Tikkoatokak Bay (Fig. 1). Landings in this area increased steadily from 1974-78 and in excess of 200 t of charr have been removed during the past five years. This stock has been under quota management since 1979. The total allowable catch (TAC) for 1979 and 1980 was 39.5 t. The TAC in 1981 was 28.5 t (Dempson 1981).

This document updates the 1980 stock assessment utilizing data from the commercial fisheries from 1977-81 and information derived from the Fraser River charr population from 1975-79.

## Stock determination

Biological and morphological studies indicated that Tikkoatokak Bay Arctic charr can be defined as one stock complex distinctly different from charr populations to the south in Anaktalik and Voisey Bay and from those to the north in the Okak and Hebron regions (Dempson 1982). Tagging investigations have shown that there is minimal interchange between inner bays from other areas although annual movement into offshore feeding areas does occur but in varying proportions. Nain Bay (Fraser River) charr contribute substantially to the Tikkoatokak Bay fishery and are considered, therefore, as part of the same stock complex (Fig. 2 and 3).

## Tagging studies

Beginning in 1979 Arctic charr have been tagged during the period of their spring seaward migration in Nain and/or Tikkoatokak Bay in order to provide information on within season movement and relative exploitation ( $\mu=\mathrm{R} / \mathrm{M}$, Ricker 1975). The weighted mean within season exploitation over two years on Nain Bay charr was $\mu=51 / 228=0.22$ ( $95 \%$ C.L. $=0.17-0.29$ ). Similarly the weighted mean within season rate of exploitation on Tikkoatokak Bay Arctic charr was $\mu=41 / 106=0.39$ ( $95 \%$ C.L. $=0.28-0.52$ ). For Tikkoatokak Bay charr caught only in Tikkoatokak Bay and in no other area, the rate of exploitation reduces to: $\mu=36 / 106=0.34$ ( $95 \%$ C.L. $=0.24-0.47$ ).

## Stock Assessment

## Catch and effort data

Catch and effort data for Tikkoatokak Bay are summarized in Table 1 for 1974-81. The highest catch occurred in 1978 when in excess of $55 t$ were removed. A quota of 39.5 t was in effect for 1979 and 1980. A further reduction of the quota in 1981 to 28.5 t has effectively reduced the high catch of 1978 by approximately $50 \%$. Catch per unit effort increased in 1981 to $351 \mathrm{~kg} / \mathrm{man}$-week but it has generally remained steady for the past four years. Average C/E from 1978 to 1981 was $350 \mathrm{~kg} /$ man-week.

Substantial changes have occurred in the weight composition of the landings. The proportion of charr over 2.3 kg (gutted head-on weight) has declined from an average of $19.1 \%$ from 1976-78 to $10.3 \%$ in 1980 and only $4.8 \%$ in 1981. Length distribution of landings, however has remained virtually constant during the past three years (Fig. 4).

Numbers at age were available from the commercial fishery since 1977 and are summarized in Table 2. Data were derived from age length keys and length frequencies and extrapolated to the total catch.

Weights at age were calculated from commercial samples and converted from gutted head-on to whole condition using the conversion factor 1.24 (Coady and Best 1976) (Table 3).

Partial recruitment rates were derived in two ways. First partial recruitment values were calculated from a matrix of fishing mortality rates generated from a cohort analysis (Rivard 1980) run on the 1977-81 data. F values were averaged at age for the years 1977-79 only. Values are listed in Table 3. In addition, partial recruitment values were calculated using Fraser River counting fence data as an index of the population. The percent at age in the Tikkoatokak Bay catch (1980-81) was compared to the percent at age from the Fraser River fence data (1975-79) (Table 4). The ratio of these percentages provides a measure of selectivity with the highest value assigned the value of 1.0 for fully recruited fish.

Yield per recruit was calculated by the method of Thompson and Bell (Ricker 1975) using partial recruitment values and mean weight at age. Natural mortality was assumed constant at 0.2. $\mathrm{F}_{\dot{0} \cdot 1}$ calculated from partial recruitment rates derived from cohort analysis was 0.425 . $\mathrm{F}_{0} \cdot 1$ calculated from partial recruitment rates derived from Fraser River fence data was 0.466 .

Total mortality $(Z)$ was calculated using the Paloheimo method where catch per unit effort at age data are required (Table 2). Average $Z$ calculated was 0.59 . Mean $Z$ during the past two seasons was 0.48 . A separate estimate of fishing mortality was also derived from tag recaptures of Tikkoatokak Bay charr. Assuming a Type I fishery:

$$
\mu=1-e^{-F}
$$

(Ricker 1975).
Rate of fishing mortality was 0.49 or 0.41 for those Tikkoatokak Bay Arctic charr caught only within Tikkoatokak Bay.

Stock projections were performed using a range of terminal fishing mortality rates $\left(F_{T}\right)$ from 0.4 to 0.6 with both sets of partial recruitment data. Although only five years of information were available, regressions of $F$ on effort produced $r^{2}$ values of $0.83,0.80$ and 0.66 for terminal $F$ values of $0.4,0.5$ and 0.6 using partial recruitment values derived from cohort analyses (Table 5). Similarly, $r^{2}$ values from the regressions of $F$ on effort using partial recruitment rates from counting fence data were $0.95,0.89$ and 0.81 for terminal F's of $0.4,0.5$ and 0.6 respectively (Table 5). Recruitment estimates for the projections were calculated from the geometric mean of the age six population numbers for the years 1977-79.

Results of the projections are shown in Tables 6 and 7. Fishing at $\mathrm{F}_{0.1}$ indicates a catch of 15.2-24.8 $t$ is available in 1982 using partial recruitment values for cohort analysis. Similarly, using counting fence recruitment rates the projected catch for 1982 is $21.3-34.9$ t.

## Discussion

Relative estimates of within season exploitation, as derived from tag recaptures, suggests a high rate of fishing in Tikkoatokak Bay. Adult stock size has undoubtedly decreased since the mid to latter $1970^{\prime}$ s, but despite the apparent high exploitation, catch per unit effort has remained quite high and constant. Similarly, size composition of landings in terms of length distribution has changed little during the past three years but there has been a decrease in the number of charr less than 50 cm and greater than 60 cm in comparison with 1977-78. Variation in mean length from 1979-81 was 0.9 cm and from 1977-81 it was 2.9 cm . There has also been a noticeable decline in the proportion of heavier fish in the catches.

This decline in stock size, coupled with an initial change in size structure but later consistency, has been observed in other exploited charr populations (Johnson 1980). Johnson (pers. commun.) suggests charr populations respond to exploitation through a community interaction which "results in a uniformity in the population, irrespective of age, so that instead of getting a population of charr of various sizes, of increasing age, we get a population of very uniform size but non-uniform age." Figure 5 illustrates the length distribution of the Fraser River adult population from 1975-79. Again there has been a decrease in the number of charr in larger length groups in comparison with 1975, but a fairly constant distribution in 1977 and 1979. Mean length has varied by only 1.3 cm for 1975 to 1979, however weight of charr at size also appears to have declined (Table 8). When age groups are superimposed on length strata a large overlap, and non-uniform distribution of age at size results (Fig. 6). Charr of any age exploited by the commercial fishery in Tikkoatokak Bay can virtually be found in any length group greater than 40 cm .

It is suggested that a surplus of pre-recruit juveniles was built up in the Nain-Tikkoatokak system during years of low exploitation (pre-1976). Owing to variations in growth rate and age at first seaward migration, many of these juveniles are still being recruited into the fishery and maintaining the high catch rates of $8-10$ year old fish. If catch had not been reduced from the 1978 level, recruitment overfishing would have undoubtedly occurred. The present quota of 28.5 t represents a substantial decline from catches and TAC's from 1977-80 and should have a corresponding effect of increasing escapement into these systems.

The present assessment was conducted using partial recruitment rates derived from two sources. Since relatively few years of data are available it is felt that the PR's generated from the non-selective counting fence data are more accurate. In addition, regressions of $F$ on effort were correspondingly higher using partial recruitment rates generated by this method. Projections for 1982 indicate that an $F_{0} \cdot 1$ catch of between $21.2-34.9 \mathrm{t}$ is available for 1982. Average total mortality obtained from the Paloheimo method was approximately $0.6(F=0.4)$ which would give a TAC of $34.9 t$. Estimated fishing mortality derived from recaptures of Tikkoatokak Bay charr caught within the same area
( $F=0.41$ ) would also yield a similar TAC. Based upon the long term projection of $F_{T}$ at 0.6 a yield of 0.827 kg (age 6 population of 41,179 ), a TAC of 35 t is recommended for 1982.
