**REPORT
ON
VHF AND UHF PATH LOSS MEASUREMENTS**

1.0 INTRODUCTION

The following report details the results of a field strength survey conducted during late January/early February, 1994, for the purpose of compiling radio-frequency field values measured along defined radial paths from radio transmitting sources. This data is intended to be compared with the results of the CRC Propagation Prediction Program.

Within the 100-2,000 MHz frequency range of interest, measurements were conducted for four 856 MHz trunking radio sources and five 88-108 MHz FM broadcast radio sources, along 1-3 radial paths from each transmitter location. Criteria for the selection of the radio sources and the specific radial paths are discussed in Section 2.0 and 3.0, respectively.

Measurements were done using roof-mounted, monopole antennas, a precision radio test receiver, and a computer control/data logging system, all mounted in a mini-van. Each measurement was triggered by a bicycle odometer wheel mounted to the back of the van. Measurements were taken every metre over an approximate span of 250 m on either side of each selected radial measurement point. Details of the methodology are provided in Section 4.0.

The test receiving antennas consisted of a roof-mounted, monopole antenna in the case of the FM broadcast signals and a roof-mounted, monopole with inclined ground plane antenna for the 856 MHz trunking radio signals. Reference radio transmitter parameters were obtained from available Industry Canada licensing documentation on each of the sources and, where possible, were verified using a direct reference measurement. This is discussed in Section 5.0.

The data collected at each point were analyzed to determine the median field and standard deviation. Terrain profiles were generated for the cross-section of each radial path. These are discussed in Section 6.0 and are included within this report.

2.0 RADIO SOURCES

The criteria for the selection of the radio sources was as follows:

- Within the range of 100-2,000 MHz, with particular interest on higher frequencies in this range
- Vertically polarized to allow for roof-mounted, monopole antenna use
- Continuously transmitting
- Located in areas where the terrain within 30 - 50 km of the transmitting site was interesting from a propagation perspective, with no local clutter, minimum urban build-up and non-excessive antenna height, such that shadowing effects would be encountered along each radial path
- Sufficiently well-characterized transmit antenna parameters to allow accurate determination of effective radiated power.

These criteria ruled out some originally-contemplated sources: UHF broadcast television (horizontally polarized), 1.7 GHz STL's (combination of incorrect polarization, uninteresting paths, general lack of potential sources), 450 MHz mobile radio (non-continuous transmitting). Two types of sources which met the above criteria were identified and utilized.

At the lower end of the frequency range of interest, five FM radio broadcast facilities, transmitting from four separate sites, were identified. These were deemed suitable due to their circular polarization, i.e., a vertical signal component, well-characterized transmitting parameters, and interesting terrain features in the vicinity. The five sources were as follows:

- CKEY-FM, 101.1 MHz, Fort Erie
- CFMX-FM, 103.1 MHz, Cobourg
- CFMX-FM-1, 96.3 MHz, First Canadian Place (Toronto)
- CKFM-FM, 99.9 MHz, CN Tower (Toronto)
- CHIN-FM, 100.7 MHz, CN Tower (Toronto)

In the mid-range of the frequency band of interest, four 856 MHz trunking radio sites operated by Motorola were selected. Along with meeting criteria such as interesting geographical locations, vertically polarized signals, etc., these sites utilize either omnidirectional or slightly directional transmitting antennas, therefore, allowing for reasonable determination of radiated power. Also of importance, each site utilizes a five frequency block of channels, of which one channel is a control channel, and which is, therefore, continuously transmitting. The four sites were located in King Township north of Toronto, Barrie, Fonthill (mid-Niagara Peninsula), and Kitchener.

Details on the parameters of each source are given in Section 5.0.

3.0 RADIAL MEASUREMENT PATHS

Having selected the transmitting sources, the selections of specific radial measurement paths were based on the following criteria.

- Minimum urban development along the paths in order to minimize urban clutter effects.
- Existence of one or more natural terrain obstructions in order to provide paths where diffraction effects would be in evidence.
- Paths directed within main beams of directional antennas such that ERP was well characterized.

Specific radial directions were selected by plotting a three dimensional terrain plot, (utilizing the CRC Topographic Database) around each site and determining the locations of the natural obstructions and high terrain elevation points. Brief descriptions of the paths chosen for each of the sites are provided below. Plots of the terrain elevation profiles are given in Appendix A2. Locations of the radial paths are shown on 1:250,000 scale topographic maps in Appendix B.

1. CKEY-FM

A single radial from this site was chosen which encompassed two significant terrain features - Fonthill, which is the highest elevation in the Niagara Peninsula area at approximately 35 km from the transmitting site and the Niagara Escarpment at approximately 65 km from the site, which provides a major terrain drop off.

2. CFMX-FM-2

This site, north of Cobourg, is situated in relatively hilly terrain. Two radials with continually undulating terrain were selected.

3. CKFM-FM/CHIN-FM

These stations are located on the CN Tower at an unusually high elevation (456 mAGL). The terrain, northward from Toronto, however, continually rises reaching a peak at approximately 35 km and, thereafter, dropping off. This provided a path with a significant terrain obstruction in the centre.

4. CFMX-FM-1

This site is located on First Canadian Place very near to the CN Tower and, therefore, the radial path northward has the same characteristics. The antenna, however, is mounted some 150 m lower and, therefore, this source would allow for direct comparison between high and low antenna elevations for the same radial path.

5. King City

Three radial paths with various significant terrain obstructions were chosen.

6. Barrie

Two radial paths, northward through fairly mountainous ski country were investigated.

7. Fonthill

Two radial paths, one of which exhibits the Niagara Escarpment as the major terrain feature and one which simply has a continually dropping terrain profile were used.

8. Kitchener

Two radial paths with reasonably undulating terrain and a single major central terrain obstruction were chosen.

4.0 TEST EQUIPMENT AND METHODOLOGY

A list of the test equipment used is provided in Appendix D. Basically, the FM radio broadcast measurements utilized a roof-mounted, adjustable, monopole antenna while the 856 MHz trunking radio measurements utilized a quarter-wave, monopole with 45° inclined ground plane, roof-mounted via a non-conducting extension of approximately 35 cm. These fed a Rohde & Schwarz ESVD precision test receiver via approximately 3 m of RG-58/low-loss flexible coax, respectively. The receiver was triggered via a bicycle wheel odometer arrangement, mounted on the back of the van and calibrated to provide a trigger signal approximately every 1 m. The test receiver was controlled via a PC computer running custom CRC software which also logged the data. A GPS unit was also connected to the PC to provide co-ordinates within the data files, at approximate 3 second intervals.

The selected radial paths were plotted on 1:50,000 scale topographic maps. At every location along the radial where an accessible road crossed the radial, measurements were taken. In general, 100 - 400 measurements points were recorded with the majority of

measurement points numbering in the 250 range. Measurements were conducted at approximately equal distances on either side of the radial/road intersection. Important features such as heavy tree cover, urbanization, building or road embankment shadowing were noted at each measurement point.

A custom program was developed to read the output data files for each measurement point (each consisting of approximately 250 individual measurements around the specific radial point) to determine the median field strength and the standard deviation about the average.

A slight deviation in this procedure was used for the FM broadcast measurements of CKFM-FM, CHIN-FM and CFMX-FM-1. In this case, the radial was run along Highway 11, which is within 2° of a constant azimuth radial line. For this set of measurements, virtually continual measurements were taken along the radial. The CKFM-FM and CHIN-FM measurements were taken simultaneously, with the monopole receive antenna adjusted to be tuned mid-way between the two frequencies and the CFMX-FM-1 measurements were taken on the return path. In the analysis, the data was broken into sections of 250 points and the median field and standard deviation calculations done on each of these sub-sets.

As well, where practical for each source, a reference measurement for the purpose of verifying the assumed ERP, was taken at a location where substantially free space measurements could be obtained. The measurements were taken over a short range (about 100 m) while examining for minimum signal level deviations verifying the free space propagation path.

5.0 REFERENCE DATA

The following sections provide the reference data and calculations for the antenna gains, source ERP's and receiver settings.

5.1 Antenna Calibration

The FM monopole antenna mounted on the van roof was calibrated as follows. Approximately 60 measurements separated by 1-2 m were taken of a mid-band (99.9 MHz) station broadcasting from the CN Tower. Measurements were taken in an open parking lot along the Lake Ontario waterfront, approximately 5 km from the CN Tower. The site was free from foreground obstructions and scattering sources such as buildings, lamp standards, etc. The measurements were then repeated using a vertically oriented, calibrated dipole antenna. The results were as follows:

Monopole: Avg Signal = 85.2 dBuV, Std.Dev. = 1.0 dB

Dipole: Avg Signal = 85.4 dBuV, Std.Dev. = 1.0 dB

It is noted that the measurements show excellent consistency and very small standard deviation, thereby indicating a relatively scattering-free environment. Since the results are within .2 dB of each other, the van/monopole antenna system is considered equivalent to that of the reference dipole. The manufacturer's published gain of the dipole is within .05 dB of an ideal, theoretical dipole.

A similar calibration was not conducted for the 856 MHz monopole due to difficulties in equalizing the line losses between the two antenna systems and the higher variability of UHF signals. Since the monopole was carefully constructed by CRC, was of simple design and since the antenna was well separated (approximately one wavelength) from the van roof, it is anticipated that the gain would be very close to the theoretical. This was calculated using a moment method analysis (CRC Tech. Memo #DRC-93-0) as equal to a factor of 2 (3 dBi). ?

The antenna factor, which is defined as the conversion in dB between measured signal level in dBuV to ambient field in dBuV/m, is defined by the following formula:

$$E = V \sqrt{\frac{4\pi\Omega}{w^2 g R}}$$

where E = field

V = voltage

$\Omega = 377 \Omega$ (free-space impedance)

w = wavelength

g = 1.64 (dipole gain)

R = 50 Ω (system impedance)

The antenna conversion factors are thereby, as given below. Line losses were measured by CRC. A nominal .2 dB miscellaneous/connector loss has been included.

| Frequency (MHz) | Theo. Ant.Factor (dB) | Gain (dBD) | Line Loss (dB) | Misc. (dB) | Total Ant. Factor (dB) |
|--------------------|-----------------------------|---------------|-------------------|---------------|------------------------------|
| 96.3 | 7.75 | - | .6 | .2 | 8.6 |
| 99.9 | | | | | |
| 100.7 | 8.10 | - | .6 | .2 | 8.9 |
| 101.1 | | | | | |
| 103.1 | 8.34 | - | .6 | .2 | 9.1 |
| 856 | 26.73 | 0.86 | .7 | .2 | 26.8 |

5.2 Transmit Parameters

The transmit parameters assumed for each radio source were those on file with Industry Canada. Antenna horizontal radiation patterns for the directional sources (King Township, Barrie, Fonthill, CKEY-FM and CFMX-FM) are contained in Appendix C.

The parameters used for each source, for each radial direction, are provided at the top of the measurement result Tables 1 through 14, given in Appendix A1. Note that ERP is defined as effective radiated power relative to a dipole.

Direct verification of the FM broadcast ERP's was generally not possible due to difficulty in obtaining a location near to the antenna with sufficient height and foreground clearance to provide free space propagation, i.e., Fresnel zone clearance. The transmission parameters and antenna radiation patterns for these types of facilities, however, are generally very well defined and it is anticipated that the actual versus assumed ERP's are well within overall system tolerances. All of these stations utilize panel antennas which are well-characterized in terms of radiation pattern and are not significantly impacted by supporting tower effects, (as are, for example, side-mounted ring-type antennas). As an example, examining the data for CKFM-FM and CHIN-FM which, theoretically, differ in ERP's by 6.7 dB, it will be noted that the actual difference is very near to this value.

For the 850 MHz trunking radio sources where free space propagation is easier to realize, a reference measurement was made at a convenient, unobstructed nearby location, where possible. The table below details the results.

| Site | Azimuth (°) | ERP (W) | Distance (km) | Expected Signal (dBuV) | Measured Signal (dBuV) | Std. Dev. (dB) |
|-----------|----------------|------------|------------------|------------------------------|------------------------------|-------------------|
| King | 330 | 51 | 4.2 | 54.8 | 52.4 | 1.6 |
| Barrie | 26 | 46 | 2.0 | 60.8 | 61.2 | 1.5 |
| Kitchener | 272 | 65 | 8.8 | 49.4 | 49.0 | 1.5 |
| Fonthill | 316 5 | 85 85 | 0.6 0.5 | 73.9 75.5 | 55.3 59.0 | 0.1 2.5 |

It is noted that Barrie and Kitchener are within 1 dB of the theoretical values. King City is within 3 dB, while Fonthill differs significantly. In the latter case, this is expected to be due to the fact that the measurement was necessarily taken very close to the antenna and, therefore, the vertical radiation pattern was a factor. Furthermore, the antenna was side-mounted on the tower and, therefore, some distortion of the theoretical horizontal pattern could be anticipated. The Fonthill data should, therefore, be used to determine general trends as opposed to absolute values.

5.3 Receiver Settings

The variable parameters of the ESVD receiver settings were frequency, IF bandwidth, sampling interval and type of detection. Under the computer control the sampling interval was automatically set to 10 ms, and the detection to average (RMS). The frequency was user set to the centre frequency of the channel under study. The IF bandwidths were set to 10 KHz for the 856 MHz radio signals (these have a nominal 16 KHz bandwidth), and 120 KHz for the FM radio signals (nominal bandwidth of 200 KHz).

6.0 DATA AND ANALYSIS

Data for each of the fourteen sources are provided in Tables 1 through 14 of Appendix A1 with accompanying terrain profiles in Figures 1 through 14 of Appendix A3. At the end of each table a graph of the measured median fields versus distance is provided along with a scatter plot of standard deviation of each point.

Appendix A2 provides representative distributions of the measured signal levels at two locations for various radials. For each radial, distributions are provided at locations of relatively low (1-3 dB) and high (6-9 dB) standard deviations, respectively. The sampling interval is 1 dB, i.e., the ordinate indicates the percent of values falling within 1 dB of the values given along the abscissa.

While detailed data analysis and correlation with path terrain characteristics is beyond the scope of this report, the following general observations are made.

The 856 MHz measurements exhibit standard deviations in the range of 2-8 dB, averaging 4-5 dB. No obvious correlations between decreased signal levels, increased standard deviations, and existence of tree cover or urbanization are apparent. The field trends do correlate with the general profile characteristics, showing definite shadow loss in obstructed locations, and increases at elevated, unobstructed locations.

The FM radio signals exhibit slightly lower standard deviations in the 3-4 dB range. The CKFM-FM/CHIN-FM field characteristics track very well with each other, exhibiting a 6-7 dB difference as expected due to the 6.7 dB ERP difference. The CFMX-FM-1 field characteristic also tracks well with the above (noting that the CFMX-FM-1 site is about 0.5 km closer to any given point than is the CN Tower), averaging about 3 dB lower than the CHIN-FM signal.

The field distributions, particularly the examples with low standard deviation, generally indicate symmetrical to slightly skewed behaviours about the medians. This would be expected in a multipath environment with a direct signal and a single dominant multipath signal. For these well-behaved distributions, the maximum fields are generally about 6 dB higher than the median (in-phase addition of direct and reflected signals) while the distribution below the median extends 6-10 dB, typifying anti-phase addition of a direct and reflected signal of slightly differing magnitudes.
