2. Preliminary paper written in conjunction with T. Benjaminsen and B. Bergfigt Norway.

## Introduction

For the past 100 years hooded seals have been hunted in their breeding areas in the west Ice which is North of Iceland, and off the eastcoast of Newfoundland. In 1974 another whelping area was rediscovered in: the David Strait (Sergeant, 1974).

The only known molting area is east of Greenland in, the Denmark Strait. It would seem that the Newfoundland and West Ice stocks molt here in June and July (Nansen, 1924; Silvertsen, 1936, Rasmussen, 1957). This theory has been confirmed by tagging studies. In 1974, loo subadult and adult hooded seals were tagged in the Denmark strait. Two of these tags were recovered in 1976 and one in 1977 during the Newfoundland hood seal hunt ( $\neq 1$ itsland pers. comm.).

Recent regulations have set a quota of 15,000 on the Newfoundand hooded seal stock, based primarily on the average catch of seals, not including Greenland and high arctic catches. A more analytical approach ( $\varnothing$ ritsland and Benjaminsen, l975a) calculated a sustainable yield of 24,000 hooded and it was recommended that this be divided into 14,000 pups, 6, 000 mature females and 4, 000 adult males. However, regulations in 1977 tried to reduce the take of adult females to less than $10 \%$ of the overall catch.

Despite the quota the average catch since 1970 has only been 11,420 seals with a low of 7,190 in 1970 and a high of 15,612 in 1975 . Indeed, it is only in one year that a level of catch equivalent to the quota was actually achieved. This fact is more related to ice conditions, and the quota and value of harp seal pups, then the size of the hooded seal population. It should also be noted that 2 or 3 hooded seal whelping patches which form up to the south of the front harp seal stock only represents a fraction of the total hooded seal herd. In fact, hooded seals whelp as single family units or small patches on Arctic ice over the whole North Atlantic. Thus recent concern by the canadian Industry that the patches along the front are being overly exploited (T. Curran per. comm.) is probably well-founded, but these concerns should not be extrapolated to the herd as a whole.

It is therefore, the purpose of this paper to evaluate the available data in light of constructing a simulation to test the validity of our present management criteria.

The age samples collected from Norwegian catches of hooded
 in 1973, 1974 ( $\varnothing$ ritsland and Benjaminsen, l975b) and in 1975 and 1976 are listed in Table l. In most of the years the samples were from the catch of two or more ships and collected without any selection to age or sex. So even through the precocious 4- year old females seem to be somewhat segregated from the older females (øritsland and Benjaminsen l975a) the samples should give a fairly good representation of the catch at eye.

Table 2 shows the total catches of hooded seals off Newfoundland and in the Denmark Strait. Out of a total of 273 , 475 hooded seals taken off Newfoundland from 1946 to 1977 Norwegian vessels have caught 69\%, Canadian vessels larger than 150 feet 24 and landsmen and small vessels 7\%. The hunt in the Denmark strait for moulting hoods in June - July by Norwegian vessels was stopped in 1960. A Danish sealing vessel made some catches herefrom 1962 to 1966 , from 1970 and on hooded seals have been sampled for scientific purpose, every second year by Marine Research Institute, Bergen; Norway.

## Production estimated by Survival Indices

Sergeant (1971) developed a method were he attempted to estimate pup production of harp seals from age samples after varying pup catch. He rated each year-class from 0 to 3 in proportion to their strength.. The average ratings were then expressed as a proportion of the maximal possible value to give a survival index ranging from 0 - 1.0 . A survival index of 0 means that production equals the catch and by plotting the survival index on pup catch the intercept of the regression line on the $X$ axis therefore gives an estimate of pup production. The method was further quantified by øritsland (1971) by dividing the frequency in sample with the frequency of the corresponding year class in a life table to produce a survival index.

The survival index method was used by $\varnothing$ ritsland and Benjaminsen (1975a) to estimate the pup production of hooded seals off Newfoundland from samples collected from 1971 to 1974.

In this paper survival indexes of 5-10 year old female hooded seals were calculated for the Norwegian samples collected from la7l to 1976 (Table 2). The index is expressed as the ratio of frequency in individual sample to average frequency. Weighted means were calculated using weights proportional to the square root of specimens in each sample. The table shows thatethe high pup catch in 1966 results in a low survival index in all samples. A low catch in 1968 gives, in all samples, a high survival indices.

The survival indexes are plotted against the pup catches in Figure l. The pup production was estimated by linear regression of survival indexes on pup catches. A G. M. functional regression (Ricker, 1973) was found to be most appropriate. The intercept of the
line on the $x$-axis gives the pup jroduction in the mid-year 1966.
Production estimates for the years 1963 to 1970 were obtained by using different periods in the regression. Table 2 shows that production from 1963 to 1970 seems to have been about stable at somewhat more than 30 thousand.

Calculation of Natural Mortality - variations with age
Pup production based on survival indices has been shown to be stable ranging from a high of 33,800 in 1964 to 30,900 in 1970 . Table 3. Between any two years within the 1963 to 1970 period, it has not varied by more than 800 animals.

Adequate samples of female hooded seals were not available. until 1971 when Norwegian catches began to be sampled on a regular basis (Table 1). These samples were used to calculate natural mortality in the following manner. First pup production in 1971 and 1972 was assumed to be similar, at 30,900 snimals. By dividing the frequency distribution by the maturity at age a distribution could be determined which was indicative of the population. Basically, this is because females recruit to the whelping areas only when they are pupping ( $\varnothing$ ritsland, 1975). After applying the fraction of reproductively successful females ( $\varnothing$ istsland and Benjaminsen, 1976) the pup production could be broken out into the appropriate age groups thus representing the total stock of females. Since the hunt occurs during a very short period.

$$
\begin{equation*}
i_{t+1}=\left({ }_{i} N_{t}-{ }_{i} C_{t}\right) \cdot X \operatorname{EXP}(-M) \tag{1}
\end{equation*}
$$

where the catch of females in year $t$ of age i is substracted from the population in year $t$ and age $i$ before the natural mortality, $M$, is applied. Thus.

$$
M=\ln \left[\begin{array}{ll}
i=24 & i=4  \tag{2}\\
\sum i N \\
i=4^{N} & \sum i=4 \\
\hline i=25 \\
i=1=5 \\
i=1
\end{array}\right]
$$

Between 1971 and 1972 the instantaneous rate of natural mortality for hooded seals was determined to be 0.124 . This value agrees well with that determined by øritsland and Benjaminsen (1975) of 0.130 for females from West Ice herd. Lett and Benjaminsen (1977) determined a similar value for harp seals of 0.114 .

Eskimo catches in Greeland also influence this estimate of natural mortality, however, it is not known which herd these catches are removed from making it impossible to include in our calculations. The catch of adults and pups only range between 2,000 and 3,000 seals (Kapel 1975) and it is unlikely that the natural mortality would be overestimated by more than $2 \%$ based on these catches.

Pup production in 1970 was estimated at 30,900 (Table 3) and this value was assumed for l971. Based on the partial recruitment, catch frequency, and fertility rate the number of females in cach age group was subsequently determined. Given that we assume this starting population, cohorts for a number of years hence can be calculatec from catch at age data using equation I. This forward projection from 1971 to 1976 was used to determine starting hunting mortality, $F$, values for virtual population analysis. F values were determined in somewhat different manner than in other virtual population methods Gulland (1965) since the catch takes place during a short period of time.

Given that

$$
\begin{equation*}
F=\ln \left[\frac{i^{N} t}{i^{N} t+1}\right] \quad-M \tag{3}
\end{equation*}
$$

by substituting equation (1) for $\mathrm{i}_{\mathrm{t}+1}$ the following equation is determined.
(4). $\quad E=-\left(\ln \quad\left(1-{ }_{i} C_{t} /{ }_{i} N_{t}\right) \operatorname{EXP}(-M)+M\right)$

The terminal or starting average hunting mortality value for 1976 was found to be 0.l01. Thus total mortality in 1976 is about 0.225 a value substantially higher than that experienced by harp seal (Lett and Benjaminsen 1977).

Since the catch. occurs before natural mortality is applied to the population the cohort sizes in the terminal years were estimated using the following equation.

$$
\begin{equation*}
i^{N}=\frac{i_{t} C_{t} \operatorname{EXP}\left({ }_{i} F_{t}\right)}{\operatorname{EXP}\left({ }_{i} F_{t}\right)-1} \tag{5}
\end{equation*}
$$

After the cohort size is determined in the terminal years the equation

$$
\begin{equation*}
i_{t}=\left(N_{t+1}+C_{t}\right) \times E \times P \quad(M) \tag{6}
\end{equation*}
$$

is applied sequentially, the cohort size within an age-group in each year depending on the cohort size within the age group the year before. Terminal cohort sizes for 25 year old hooded seals was determined by averaging the hunting mortality values for ages 6 to 25 and applying these using equation (5) to the catch of 25 year old animals. The population in 1971 was then determined based on these calculations (Table 4).

Historical Population Estimates and Estimates of Mean Age of Whelping
Catches for this population have been recorded since the second world War (Table l) although little was done of a scientific nature until 1971 . If one assumes that partial recruitment in the fishery has not changed much over the period however, this data becomes very interesting and useful.

One important factor that, must be considered is the proportion of Newfoundland and West Ice seals that molt in the Denmark Strait. since these two herds are surmised to be of about equivalent size it was assumed that $50 \%$ of that catch in the Denmark strait comes from the Front herd and $50 \%$ from the west Ice herd. All age groups are fully recruited in the molting patch, while partial recruitment in the whelping area is $0.019,0.412,0.558$, and 1.000 and so on, for age groups $1,2,3$ and 4 etc. Furthermore, only the female sector of the hunt is considered.

Since the projection goes back through time, recruitment to the model is through the oldest age group. This is done with a random number generator (77-33), with the value being passed upon estimates between 1970 - 1976.from cohort analysis. The catches in individual years are broken over the age groups in relation to partial recruitment and the population structure. Pup production is calculated from the catch of pups and natural mortality, which was assumed to be the same as that for adults. The following values were calculated with the simulation.

| YEAR | ESTTMATED |  | ESTIMATED |
| :---: | :---: | :---: | :---: |
|  | PUP | PRODUCTION | 1+ Female Pop. |
| 1946 |  | 27110 | - |
| 47 |  | 24641 | 74065 |
| 48 |  | 31438 | 70607 |
| 49 |  | 29500 | 65785 |
| 1950 |  | 26264 | 68107 |
| 51 |  | 31714 | 67640 |
| 52 |  | 22582 | 59176 |
| 53 |  | 24495 | 58442 |
| 54 |  | 23545 | 59227 |
| 1955 |  | 24977 | 57748 |
| 56 |  | 28202 | 57586 |
| 57 |  | 21443 | 54239 |
| 58 |  | 26319 | 53479 |
| 59 |  | 25910 | 52592 |
| 1960 |  | 25103 | 54524 |
| 61 |  | 23373 | 55540 |
| 62 |  | 21867 | 58140 |
| 63 |  | 25116 | 60199 |
| 64 |  | 23770 | 61105 |
| 1965 |  | 22651 | 58957 |
| 66 |  | 33369 | 60035 |
| 67 |  | 35217 | 55511 |
| 68 |  | 36166 | 57392 |
| 69 |  | 34830 | 65769 |
| 1970 |  | 30900 | 64465 |

Tests were conducted to determine how sensitive the model was to different level of terminal-age-recruitment. It appears that the model was almost totally insensitive to these values, and cohort size but age 5 was much more dependent on the catch data. It can be seen from the forgoing table that pup production varied considerably, and this it not related to the terminal age recruitment.

One interesting feature of the table is the drop in pup production prior to 1966 . The feature is not explainable by poor assumptions concerning the Denmark strait hunt since there is essentially no hunt in this area following its closure in l96l. Thus either a dramatic change in productivity of the herd suddenly took place, or breeding females emigrated to the Newfoundland whelping area or the total kill of pups is not recorded. However, for what ever reason, it is our belief that data before 1966 is not comparable with that afterwards.

The annual number of $1+$ females is plotted in Fig. 2 between. 1947
and 1970. It would seen that the stock has been slowly building up since 1960 primarily due to the closure of the Denmark Strait hunt in l961. This is not surprising when one considers that the average kill between 1947 and 1960 was 23232 animals. Even more significant is the fact that the reduction in kill was l+ animals, probably a substantial number of breeding females. This is possibly the cause of the change in productivity which occurred in 1966.

It has been proposed by Sergeant $(1966$, 1973) that mean age of whelping for harp seals is related to the size of the population. Lett and Benjaminsen (1977) and Capstick and Ronald (1976) upon further analysis found this to be indeed the case. Øritsland (l973) presents data on the maturity and reproductive performance of hooded seals in which he uses a combined sample between 1967 and 1972 . His conclusions are as follows.

| AGE | 1963 | (øritsland, 1974) | $1969^{\circ}$ | (øritsland, 1973) | 1971 | study) |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| 3 | 0.05 |  | 0.12 |  | 0.22 |  |
| 4 | 0.48 |  | 0.58 |  | 0.89 |  |
| 5 | 0.75 |  | 0.75 |  | 0.99 |  |
| 6 | 0.90 |  | 0.86 |  | 1.00 |  |
| 7 | 0.96 |  | 0.97 |  | 1.00 |  |
| 8 | 0.98 |  | 0.98 |  | 1.00 |  |
| 9 | 0.98 |  | 0.98 |  | 1.00 |  |
| 10 | 1.00 |  | 1.00 |  | 1.00 |  |

Unfortunately, øiitsland's (1967-1962) sample was removed from the breeding patches, thus only precocious females would be in the sample. He claims his method of counting persistent scars from the corpus luteum is valid since these scars will persist for three years after they have formed. By examining the ovaries of a mature female and counting the number of scars one can evaluate when the animal first matured. Unfortunately there is no wáy of counting missed pregnancies or being sure when the animal matured after it has ovulated 4 or more times. Thus there is a tendency to overestimate the mean age of maturity.

The 1970 - 1972 sample was taken from the moulting patch and therefore could be evaluated for mature or non-mature animals since all age groups were totally represented. Thus the only sample in which we can have complete confidence are those presented for the first time in this study.

Due to the lack of information iterative numeirical method was developed to estimate the mean age and standard deviation of maturity. Using the age frequency and pup production generated by the program to calculated historical population size, a matưity ogive was fitted to the $1+$ female population until the number of pups corresponded to the predicted pup production by less than lo animals. If the required pup production meant the animals less than the age of 3 would have to mature then the standard deviation of the maturity ogive was reduced by a designated increment and the process was reiterated until a suitable fit was obtained. The initial starting ogive and standard deviation was that of $\varnothing$ ritsland (1973). It was felt that this was a maximal position for the ogive, and if the mean age of maturity did get greater it was unlikely that the standard deviation would change. Results were obtained.from 1947 to 1970 .

Two facts were striking. First the standard deviation of maturity, and the mean age of maturity were highly correlated, and that again factors prior to 1966 where different than those afterwards. In other words; mean age jumped from 4.3 yrs. in 1967 to 5.5 yrs. in 1966 , for no apparent biological reason:

If maturity, as argued by Lett and Benjaminsen (1977), is a function of the growth rate of hooded seals in the juvenile stages there should be some lag between the position of the ogive and population size of $1+$ seals, if indeed there is a density dependent mechanism. This relationship is shown in Fig. 3. It would appear that minor changes in the $1+$ female population lead to changes within the position of maturity ogive. That is to say a 9\%. increase in the stock size caused a 24\% increase in the mean age of maturity. For harp seals a 100\% increase in stock size lead to a $31 \%$ increase in the mean age of maturity (Lett and Benjaminsen, 1977). The mechanism and reason for this is yet to be elucidated.

## Numbers at age

Numbers at age were determined by projecting the 1971 population forward using the catch data in Table 4: Each year before that catch, a maturity ogive was applied to the population to calculate pup production which was subsequently divided by two, to give the number of female pups. Equation $I$ was used to project the population ahead.

Maturity, a density dependent function of the population 3 years previous, is given by the equation.
(7) Mean Age ${ }^{t}=1.222 \times 10^{-4} \times 1$ POP - 3.337
where MEAN AGE is the mean age of maturity, and $L$ pop is the population lagged by 3 years.

The standard deviation of the maturity ogive is calculated by

$$
\begin{equation*}
S D=0.466 \times M E A N A G E-0.9245 \tag{8}
\end{equation*}
$$

Mean ages of maturity are given in table 5 , in addition to numbers of age and pup productions. The population has declined and risen again to a level seen in the late 40's and early 50's. The estimated number of pups in 1977 is 30930 for a total population of 66546 lt females. Since 1971 the population has achieved a certain level of stability. Pup production between 1971 and 1972 dropped from 33497 to 26827 primarily due to the increase in population size between 1968 and 1969. This effected the maturity ogive such that the mean age of maturity increased from a predicted 3.68 years in 1971 to 4.70 in 1972 .

## Construction of Simulation

The simulation was written in $A$ Programming Language and is represented in the flow chart in Fig. 4 .

The program initiated by entering in the 1977 population size, l+ female population size 3 years earlier and level of fishing mortality for $1+$ seals and pups. The number of years to be simulated constrains the internal clock.

The number of pups are calculated using equations 7 and 8 and applying the results from

$$
\begin{equation*}
M A T \leftarrow \phi[(A G E-M E A N A G E) / S D] \tag{9}
\end{equation*}
$$

to the total population. The number of pups and $1+$ seals killed are then calculated using the partial recruitment

| AGE | 1 | 2 | 3 | 4 | 5 | 6 |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: |
|  | 0.000 | 0.000 | 0.019 | 0.412 | 0.558 | 1 |

the population is then updated using
(10) $N_{t+1}=\left[N_{t}-N_{t} \times \operatorname{EXP}\left(-\partial_{t} F_{t}\right)\right] \times \operatorname{EDP}(-M)$.
and the pups and adults are shifted along one year in the numbers at
age vector.
Different factors of interest are accumulated and printed out when the clock time has expired.

## Results of the Simulation

The simulation was used to generate different Shaeffer type curves for varying levels of pup catch and l+catch (Fig. 5). Maximum sustainable yield for the stock is about 20,000 pups where there is not hunting of older.females. This MSY level for pups declines as more females are removed. The MSY population level wíh no older female catch is about 55, 000 i+ females. Because both adult females and pups are removed it may be impossìle to achieve the highest msy level. In addition,
because of the lack of sound data our management objectives should be more conservative and our objective should be more likely $2 / 3$ FMSY (Doubleday, 1976). Implications of different strategics are shown in fig. 2 A low $F$ on adult females of 0.05 and $F$ on pups of 0.35 allows the population to stay stable. By dropping the hunting mortality to 0.025 on adult females, which is closer to that noted for harps to $2 / 3$ FMSY population level will be achieved about 1984 . This means a catch of 9, 200 pups and $8001+$ females. This would make the total TAC for 1978 ll, 000 hooded seals if the 1977 sex ratio in the catch is maintained. This means by 1984 the catch of hooded pups could be 12,000, with an additional $1,0001+$ females. This would mean a future TAC of about 14,000 seals, and this value could rise as our data, and confidence in prediction improves.

Total catch of hooded seals off Newfoundland and in the Denmark Strait from 1946-1977

Figure 1. Relationship between survival index and pup catch between. 1961 and 1971. Average production for the period is about 33,000 pups.

Figure 3. Relationship between mean age of maturity and $1+$ female population size lagged by 3 years. Dark dot is a measured value while open circles are values determined using numerical techniques.

Figure 4. Flow chart of $A P L$ program simulating hooded seal population dynamics.
