## Foreword

This series documents the scientific basis for the evaluation of aquatic resources and ecosystems in Canada. As such, it addresses the issues of the day in the time frames required and the documents it contains are not intended as definitive statements on the subjects addressed but rather as progress reports on ongoing investigations.

## LIST OF TABLES

Table 1. Importance of northern shrimp in the Greenland halibut and redfish diets, according onthe period and length class considered. For each period / length class combination, thefrequency of occurrence (Focc), the mass contribution (MC, in \%), the partial fullness index(PFI) and the contribution to the $\mathrm{TFI}(\% \mathrm{TFI})$ of the northern shrimp in the N stomachs availableare provided.29
Table 2. Percentile of the cumulative distribution of male and female shrimp biomass per four- year period and per fishing area as a function of depth ( m ), bottom water temperature and dissolved oxygen saturation. ..... 31
Table 3. Landing (L) and total of allowable catch (TAC) by shrimp fishing areas: Estuary (SFA 12); Sept-Iles (SFA 10), Anticosti (SFA 9) and Esquiman (SFA 8). ..... 35
Table 4. Number of observations, catch (kg), effort (h), catch per unit of effort (kg/h) and its standard error (SE), percentage (\%) of the landing corresponding to the observations, landing ( t ) and nominal effort ( h ) by fishing area (SFA) and by year. ..... 36
Table 5. Catch (t) per month by fishing area (SFA) and by year. ..... 40
Table 6. Effort ( h ) per month by fishing area (SFA) and by year. ..... 44
Table 7. Standardised catch per unit of effort and its standard error, landing and standardised effort, by fishing area and by year ..... 48
Table 8. Number of samples of the commercial catches and number of samples per 1,000 tons of landing, by fishing area (SFA) and by year. ..... 52
Table 9. Weighting factors used to estimate the numbers at length by fishing area (SFA), by year and by month. The catch corresponds to the landing that is adjusted for the proportion (ratio) of P. borealis in the samples. The origin (month, year) of the samples used for the estimated is also indicated ..... 53
Table 10. Commercial catches (in million) by fishing area and by year. M: males, Fp: primiparous females, Fm: multiparous females. ..... 55
Table 11. Number per unit of effort by fishing area and by year for the summer season (months of June, July and August). M: males, Fp: primiparous females, Fm: multiparous females. ..... 57
Table 12. Mean catch (kg/km²) and standard error by year, for males and females for the whole studied area ( n : number of stations). ..... 59
Table 13. Mean catch ( $\mathrm{kg} / \mathrm{km}^{2}$ ) and standard error by year, for males and females by fishing area ( n : number of stations). ..... 60

## LIST OF FIGURES

Figure 1. Shrimp fishing areas (SFA) in the northern Gulf of St. Lawrence: Estuary (SFA 12);
Sept-Iles (SFA 10); Anticosti (SFA 9); Esquiman (SFA 8). ................................................... 99
Figure 2. Life cycle of northern shrimp in the Gulf of St. Lawrence. ........................................... 99
Figure 3. Proportion of egg-bearing females and females in maturation in the catch of females depending on the day of the year for the samples collected in 2020 and 2021 in the area of Sept-lles. The bottom panel shows the years 1990-2020 in gray and 2021 in red

Figure 4. Day of the year where $50 \%$ of female shrimp were maturing (maturation), where 50\% had spawn there eggs (spawning) and where 50\% of females had released larvae (hatching) from samples collected in the area of Sept-lles from 1990 to 2021. The solid horizontal lines represent the average for the 1990-2019 period.
Figure 5. Biomass (kg per tow) of the main predators of northern shrimp in the northern Gulf of St. Lawrence. The color code represents the value of the anomaly, which is the difference between the weight the CPUE and the average of the time series divided by the standard deviation of that average for each species.

Figure 6. Mean weights per 15 minutes tow observed during the survey in August in the
northern gulf for northern shrimp and redfish......................................................................... 103
Figure 7. Mean weights per 15 minutes tow observed during the survey in August in the northern gulf for northern shrimp and redfish per fishing areas. 104

Figure 8. Northern shrimp and redfish catch rates (kg/15 minutes tow) distribution during the survey in August 2021 in the northern gulf.

Figure 9. Biomass distributions of northern shrimp (in grey) and redfish (in red) as a function of depth observed during the August DFO survey by fishing area.

Figure 10. Mean mass contribution (\% mass) of northern shrimp to the Greenland halibut diet, according to the period and length class considered. The values above the bars correspond to the number of stomachs used for the analysis with the percentage of those being empty. 108

Figure 11. Mean mass contribution (\% mass) of northern shrimp to the redfish diet, according to the period and length class considered. The values above the bars correspond to the number of stomachs used for the analysis with the percentage of those being empty.

Figure 12. Fishing sets where redfish stomachs were collected for the period 1993-2021. A total of 8,491 stomachs were used for the analysis. The geographic location of each of them allowed the spatial analysis of the redfish diet. Red polygons represent the contours of the commercially fished northern shrimp fishing areas calculated from VMS data. 110

Figure 13. Estimated a) annual Redfish biomass and b) Redfish consumption of Northern Shrimp by length class for the following periods: 1997-1999, 2015-2018 and 2019-2021. The values provided in the upper part of the panels are total estimated consumption for a given year. An "x" symbol denotes < 20 stomachs collected for a given length class. Estimating annual consumption for these length classes was identified as not representative due to small sample sizes.

Figure 14. Total annual consumption estimated of northern shrimp by redfish. For the dots in blue, shrimp consumption was estimated from consumption data for the closest period since no stomach contents were available.
Figure 15. Water temperatures in the Gulf by bio-region. Average surface temperature for the months of May to August (1982-2021) (red lines). Average temperature per layer, at 150, 200
and 300 m (green lines). Index of the minimum temperature of the cold intermediate layer adjusted to July 15 (blue line). ..... 113

176
Figure 60. Harvest guidelines by fishing area. The projected harvest for 2022 is shown in view of the main stock indicator in 2021. 177

Figure 61. Index of the exploitation rate by fishing area and by year. The solid horizontal line represents the 1990-2010. For Estuary, the index includes shallow strata added in 2008. 178

Figure 62. Current state (2020-21) of the environment for the different northern shrimp stock of the GSL (A-D) compared to the conditions observed during the period considered to define the precautionary approach (1990-2010). The water temperature at the depth corresponding to the median value of the shrimp biomass distribution ( 150 m in the Estuary and 250 m in the other areas, dotted horizontal line) is used as an indicator variable of the state of the environment. For each stock (A-D), the top figure presents the density distribution of temperature values over the
period considered for the stock assessment (1990 to 2021), while the bottom figure presents the temporal variations/trends in temperature over the same period. 179
Figure 63. Precautionary approach for GSL northern shrimp stocks. The current harvest control rule (HCR) (red, yellow and green cross line) is used to determine projected harvests in 2022 without considering changes in the environment (status quo). The adjusted HCR for the increase in bottom water temperature (grey cross-sectional line) is obtained by multiplying the current HCR parameters by the environmental conditioning factor (ECF) calculated for each stock (Table 25). The adjusted HCR is used to determine the harvest conditioned on the state of the environment in 2020-21. The vertical lines represent the limit reference point (red line), the upper reference point (green line) and the stock status in 2021 (hatched black line).

## LIST OF APPENDICES

Appendix 1. Plan de recherche stratégique du MPO pour la crevette nordique de l'estuaire et du golfe du Saint-Laurent............................................................................................................. 193

#### Abstract

The Estuary and Gulf of St. Lawrence northern shrimp (Pandalus borealis) stock status is determined every year by examining many indicators from the commercial fishery and the research survey. This document presents the data and methods that were used to produce the commercial fishery statistics from 1982 to 2021 and the indicators from the survey from 1990 to 2021. In addition, the document presents some ecosystem characteristics observed in the estuary and the northern Gulf of St. Lawrence. These can have an impact on the dynamics of northern shrimp stocks through, among other things, effects on spatial distribution, growth, reproduction and trophic relationships. The elements of the precautionary approach are also presented in this document.

## INTRODUCTION

The northern shrimp (Pandalus borealis) fishery began in the Gulf of St. Lawrence in 1965. The exploitation is conducted by trawlers in four shrimp fishing areas (SFA): Estuary (SFA 12), SeptIles (SFA 10), Anticosti (SFA 9) and Esquiman (SFA 8) (Figure 1). The number of active licences for northern shrimp fishing in the Estuary and Gulf was 114 in 2021. Operators are from five provinces and seven First Nations communities.

Resource status is assessed by looking at various indicators from the commercial fishery and the DFO research survey for each of the four northern shrimp fishing areas. This document provides an update on the data and methods that were used to produce commercial fishery statistics between 1982 and 2021 and survey indicators between 1990 and 2021. The previous research paper was that of Bourdages et al. (2020).

Shrimpers must also keep a log book, have their catches weighed at dockside, and agree to have an observer on board at the Department's request ( $5 \%$ coverage). The season begins on April 1 and ends on December 31. The fishery has been managed by TAC (total allowable catches) since 1982, and the traditional fishers have had individual quotas since the mid-1990s. The fishery management measures include the imposition of a minimum mesh size ( 40 mm ) and, since 1993, the compulsory use of the Nordmore grate, which significantly reduces groundfish bycatches and a protocol to limit small fish bycatch is in place since 2014 for the small groundfish (cod (Gadus morhua), redfish (Sebastes spp.) and Greenland halibut (Reinhardtius hippoglossoides)). Use of the Vessel Monitoring System (VMS) has been mandatory since 2012. These different data sources are used to describe fishery statistics, the distribution of fishing effort, the catch per unit effort, the numbers at length in the commercial fishery and the bycatches.

Every year since 1990, a trawl research survey is conducted in the Estuary and northern Gulf of St. Lawrence (nGSL) from a Department of Fisheries and Oceans (DFO) vessel to assess the abundance of several species, including shrimp. This ecosystemic survey aims to describe the biodiversity of Gulf species and the physical and biological oceanographic conditions. It is the main source of fishery-independent data for the stock assessment of northern shrimp in the nGSL. It also describes northern shrimp distribution, estimates its stock abundance and biomass, and reveals its population dynamics. The survey is deemed to effectively cover the entire distribution range of $P$. borealis in the nGSL. Northern shrimp is typically confined to bottoms lying below the cold intermediate water layer at depths greater than 150 m .
The essential elements for establishing a precautionary approach were adopted in 2012 (Savard 2012). The main stock status indicator is calculated using the male and female indices obtained from the commercial fishery in the summer (number per unit effort for June, July and August) and from the research survey (abundance in August). Reference points were determined and harvest guidelines were established according to the main indicator and its position in relation to the stock status classification zones (healthy, cautious and critical). The guidelines are in keeping with the precautionary approach. Once the harvest has been projected, Fisheries Management applies decision rules to calculate the TAC (Desgagnés and Savard 2012; Bourdages and Desgagnés 2014).

This document also describes several environmental and ecosystem characteristics observed in the nGSL which can have an impact on the dynamics of northern shrimp stocks by affecting spatial distribution, growth, reproduction and trophic relationships.

## BIOLOGY AND ENVIRONMENT

Out of the 27 shrimp species listed in the Estuary and northern Gulf of St. Lawrence, the northern shrimp is by far the most abundant (Savard and Nozères 2012). Shrimps are forage species (Policy on New Fisheries for Forage Species). They play a key role in the ecosystem, acting as an intermediary in the transfer of energy from the lower trophic levels (e.g., zooplankton) to the higher ones (predators such as fish, marine mammals and seabirds). Ecological relationships (e.g., predator-prey and competition) must be maintained among the species affected directly or indirectly by the fishery within the bounds of natural fluctuations in these relationships.

## LIFE CYCLE

The northern shrimp, Pandalus borealis, is a protandrous hermaphrodite species. In other words, individuals first reach sexual maturity as males, then change sex and become females. This feature of the life cycle is very important for the development of harvest strategies since larger individuals targeted by the fishery are the bigger male and female.

In the GSL, shrimp larvae hatch in the spring, in April or May and remain pelagic for several months (Figure 2). At the end of the summer, larvae increasingly resemble adults and adopt suprabenthic (bottom-based) behaviour. These postlarvae and juveniles are too small to be caught by commercial fishing trawls. Juveniles reach male sexual maturity during their second year. Spawning occurs in the fall and males may spawn 2 or 3 years prior to changing sex, which occurs in winter at age 4 or 5 , at around 21 mm carapace length. Newly transformed females are easily recognized in spring and summer commercial catches as they have retained some male sexual traits. These females are called primiparous females and spawn the very next fall (September or October) after the sex change. Females carry their fertilized eggs under their abdomen during the incubation period which lasts about 8 months. The larvae hatch the following spring. Spawning females that survive reproduction are recognizable to those who have never spawned and are called multiparous females (Hansen et Aschan 2001). In fact, primiparous and multiparous females can be distinguished by morphological characteristics (sternal spines) that disappear in the prenuptial moult. Females can spawn at least twice and the estimated longevity of GSL shrimp is about 7 years.

## REPRODUCTIVE CYCLE

Environmental conditions influence the reproductive cycle of shrimp. Spring hatching must be synchronized with the spring phytoplankton bloom. In addition, bottom water temperatures influence the duration of egg development on the female abdomen. Different populations of northern shrimp ( $P$. borealis) have adapted to local temperatures and bloom times, matching egg hatching to food availability under average conditions (Koeller et al. 2009). However, this strategy is vulnerable to interannual oceanographic variability and long-term climate change.

Monitoring of the reproductive cycle in the area of Sept-Iles is made from samples collected during fishing (see section commercial catch sampling). The proportion of egg-bearing females (females carrying eggs under the abdomen), the number of egg-bearing females on the total number of females, is determined for each sample. As the proportion of females in maturation is determined by comparing the number of female with green head compared to the number of females excluding egg-bearing females. The date in fall when $50 \%$ of females are carrying eggs (spawning) as well as the date in spring when $50 \%$ of females have released their eggs (hatching) are determined based on the adjustment of the logistic function (Figure 3). The date when $50 \%$ of females are undergoing maturation is also determined (Figure 3).

The bottom waters of the GSL where the northern shrimp are found have warmed in recent years, so we expected to see changes in the reproductive cycle. Maturation of females normally takes place at the end of June, from 2013 maturation began to be delayed in time and in 2021 maturation took place at the end of July, which is one month later than normal (Figure 4). Thereafter, normally spawning takes place at the end of September, but it was delayed by more than 25 days in 2015 to 2017. From 2018 to 2021, maturation and spawning took place two weeks earlier than in 2017, a return to dates closer to normal. We know that in August of the last four years, part of the female population has moved to shallower depths where the water is colder, which could perhaps explain this return to normal. The hatching of larvae in the spring is more stable in time, around the end of April to coincide with the start of the spring phytoplankton bloom.

Changes in shrimp phenology appear to be related to increasing deep water temperature. Maturation and spawning are delayed by several days and larval development time is shorter. Thus, the timing of larval hatching varies little and remains synchronized with the spring bloom of phytoplankton.

## BEHAVIOUR

Shrimp start being caught by commercial trawls when they are males and reach a carapace length (CL) of about 15 mm . The probability of trawl capture increases with size, and individuals are fully recruited to the fishery at about $22 \mathrm{~mm}(\mathrm{LC})$. Therefore, the proportion of male and female individuals caught by fishers varies according to the catch period and location. Indeed, shrimp migratory movements are well known to fishers, who have adapted their fishing patterns to their benefit. Fishers typically try to maintain high catch rates and maximize catches of large shrimp while minimizing bycatch of other species.
Every year, shrimp migrate to reproduce. In late fall and early winter, berried females (females carrying eggs under the abdomen) begin to migrate to the shallower areas of their distribution range. In spring, they gather at sites suitable for releasing the larvae while the males are still scattered throughout the distribution range. Fishers take full advantage of this spring gathering of berried females to obtain high yields. Once the larvae have been released, the females molt and then disperse to deeper areas ( 200 to 300 meters) of the distribution range. Shrimp are also distributed differently according to the age of individuals. Typically, young shrimp are found in shallower areas, often at the heads of channels, whereas older individuals, females, are found in deeper waters. Young shrimp concentrations in shallower water are also denser than large shrimp concentrations in deep water.
The composition of spring commercial catches often closely reflects this distribution pattern. Because spring catches occur in shallower water, they often consist of 2 groups of individuals: berried females and very small males.
Shrimp also perform daily vertical migrations. They leave the bottom at night to rise in the water column to feed on plankton, and then return to the bottom during the day. The scale of vertical migrations varies depending on the individual's developmental stage and local conditions. For example, small shrimp appear to leave the bottom earlier and rise higher in the water column than do larger females. Although yields may be lower at night, the mean catch size should be higher because of the lower proportion of males in catches. What's more, it may be advantageous to fish at night to avoid bycatch of capelin, which also leaves the bottom at night.

The variations in female sizes follow an east-west gradient, the smallest being observed in the Esquiman Channel and the largest, in the Estuary. It is worth noting that, as individual fecundity increases with size, egg production by an equal number of females will theoretically be lower in the east. The number of individuals for a single unit of weight also varies by SFA. The number
of shrimp per kg depends on 2 factors: the fishing pattern influencing the proportion of males in catches; and, the mean size of females. The number of shrimp per kg is increasing from west to east because the proportion of males in commercial catches is increasing while the size of females is decreasing.

## PREDATORS

The ecosystem, dominated by groundfish until the early 1990s, has transitioned to an ecosystem dominated by forage species. Thus, following the decline in the abundance of large groundfish species, the shrimp population increased from the 1990s to the 2010s. Redfish and Atlantic halibut are currently increasing in abundance whereas northern shrimp and Greenland halibut are declining (Figure 5). Three strong cohorts (2011, 2012 and 2013) of deepwater redfish (Sebastes mentella) have contributed to the increase in redfish abundance since 2013. The redfish population now has a higher biomass than in the early 1990s (Figure 6-7). The 2011 cohort, which is the most abundant, now has a modal length of 24 cm and is distributed throughout the deep channels of the northern Gulf and to a lesser extent in the Estuary (Figure 8-9).

Trophic changes could be observed in the coming years, with shrimp forming part of the diet of many species.

## Predator diets

Redfish (species not specified) and Greenland halibut are the two main predators of northern shrimp in the GSL (Savenkoff et al. 2006). Stomachs from these predators were collected at different times during missions on board DFO vessels. The stomachs were analyzed in the laboratory and the data archived in a database. Diet analysis was conducted according to the methodology detailed in Ouellette-Plante et al. (2020).
Greenland halibut has a diverse diet. The composition of the diet of these fish varies with their size (Gauthier et al. 2021). Nearly 20,500 stomachs of Greenland halibut have been collected over the past three decades. For the diet analysis, the stomachs were sorted into three groups by period (1990s, 2000s and 2015-2021) to determine whether consumption of northern shrimp has changed over time. Findings showed that northern shrimp comprise a very small part of the diet of one-year-old Greenland halibut (less than 20 cm long), contributing $<1 \%$ to the total fullness index (TFI), regardless of the period (Table 1, Figure 10). Northern shrimp are more commonly observed in the stomach contents of two-year-old Greenland halibut ( $20-30 \mathrm{~cm}$ ). This increasing frequency of occurrence is observed across the periods studied, rising from $1 \%$ in the 1990s to $3 \%$ in the 2015-2021 period. The TFI follows a similar pattern: $3 \%$ during the 1990 s, $5 \%$ in the 2000 s and $9 \%$ in the most recent period. For Greenland halibut $\geq 3$ years old (longer than 30 cm ), northern shrimp alone accounts for more than 10\% of the Greenland halibut's total fullness index, which is significant, considering the tens of different prey items that have been observed in halibut stomachs over the years. Northern shrimp was a more important component of the diet of Greenland halibut during the 2000s than during the other two periods. It should be noted that the abundance of northern shrimp in the GSL was at a peak in the 2000s (Gauthier et al. 2021).

The diet of small redfish is based on zooplankton, with redfish consuming progressively more shrimp and fish as their length increases. (Senay et al. 2021). Unlike the case for Greenland halibut, no redfish stomach content data are available for the 2000s. The number of stomachs reported in the ecosystem surveys conducted during the 1990s, 2015-2018 and 2019-2021 periods were $3,3213,120$ and 2,050 stomachs, respectively (Table 1, Figure 11). The recent
period (2015-2021) has been divided into two to help visualize potential changes in the diet of redfish according to the evolution of the size of the stock.

For redfish less than 25 cm long, northern shrimp were present in less than $1 \%$ of the stomachs analyzed, regardless of the period. For redfish 25 cm and longer, during the 1990s the occurrence of northern shrimp in the diet increased with the size of the fish, from $1.5 \%$ to over $20 \%$ for fish longer than 45 cm . For redfish > 25 cm , the occurrence varies between $5.5 \%$ and $10 \%$ for 2015-2018 and between $2.6 \%$ and $14.5 \%$ for 2019-2021. Shrimp consumption increases with length only for the 2019-2021 period with a maximum occurrence of shrimp in fish of 35 to 40 cm in length. A significant decrease in occurrence is then observed for redfish over 40 cm . The mass contribution (MC) and TFI of northern shrimp were low ( $<6 \%$ ) in the diet of redfish less than 25 cm long. For redfish longer than 25 cm , during the 1990s the TFI increased with length from 10 to $21 \%$. For the most recent period, the TFI of Northern Shrimp for 2015-2018 is the highest for the $25-35 \mathrm{~cm}$ and $30-35 \mathrm{~cm}$ length classes. It is estimated at $26.5 \%$ and $29 \%$ respectively, while it is less than $13 \%$ for redfish over 35 cm . For 2019-2021, the TFI of northern shrimp for redfish less than 35 cm is slightly lower than for 2015-2018 but increases thereafter to reach $56 \%$ for redfish between 35 and 40 cm . It then decreases for 40 to 45 cm fish to reach a similar value ( $\sim 25 \%$ ) for the 25 to 30 cm and 30 to 35 cm classes. Northern shrimp seems to play a more important role in redfish over 35 cm for the 2019-2021 period than the 2015-2018 period.

Based on the diet of redfish, annual consumption of northern shrimp (Q) was estimated for the years 2015 to 2021 in comparison with the 1997 to 1999 period (before the advent of the strong 2011 to 2013 cohorts). Consumption was calculated using the following equation:

$$
Q=B \cdot P \cdot \frac{Q}{B}
$$

where $B$ is the redfish biomass estimate (based on the DFO ecosystem survey), $P$ is the proportion (based on MC) of northern shrimp in the redfish diet and $Q / B$ is a theoretical redfish consumption ratio. The $Q / B$ ratio values stem from the ecosystem models available for the nGSL for different periods: 1.036 for the 1990s and 0.75 for recent years (Savenkoff et al. 2004; Savenkoff and Rioual [DFO, unpublished data]).
Redfish captured for the purpose of studying their diet are representative of the entire northern Gulf and the Estuary, which encompasses the areas fished by shrimpers (Figure 12).
Consumption estimates were derived on the basis of redfish length classes ( 5 cm intervals), and were then added together to obtain a value for total consumption. Consumption was roughly 10,000 t between 1997 and 1999; since 2017, this value has risen every year, increasing from $44,800 t$ to $214,000 t$ in 2021 with the exception of 2020 where consumption was lower than the previous year (Figure 13 and Figure 14). This difference can be explained by the increase in length of strong redfish cohorts and the increasing proportion of northern shrimp in the diet of redfish. The level of uncertainty surrounding these estimates is high. Sampling redfish stomach contents is difficult owing to the regurgitation issues caused by rapid changes in pressure that occur as the trawl is raised from the depths. In addition, redfish biomass estimates from the scientific survey are relative, as the values are not adjusted for trawl catchability. Lastly, the values of the $Q / B$ ratios used to estimate consumption derive from ecosystem model estimates, not from actual measurements of redfish energy requirements based on length. Although these numbers are not precise, it is clear that northern shrimp consumption has increased in recent years. Moreover, because the redfish population is continuing to expand, redfish predation will continue to have an impact on northern shrimp in the coming years. However, the impact of this phenomenon may be lessened if the spatial overlap between northern shrimp and redfish
diminishes owing to the expected migration of adults $S$. mentella individuals to depths of over 300 m .

## ENVIRONMENTAL CONDITIONS

The deep-water layer (>150 m) of the GSL originates from the mixing of cold, less saline and well-oxygenated waters from the Labrador Current and warmer, more saline and less welloxygenated waters from the Gulf Stream. These waters meet outside the Gulf of St. Lawrence, entering through the Laurentian Channel and flowing to the heads of the Esquiman, Anticosti and Laurentian Channels. The flow of water between Cabot Strait and the head of the Laurentian Channel takes around three to four years. In recent decades, waters from the Gulf Stream have comprised a larger proportion of the mix of waters entering the Gulf, which has led to an increase in water temperature and oxygen depletion in the bottom waters of the GSL (Galbraith et al. 2021).

In 2021, temperatures at 150, 200, 250 and 300 m have warmed reaching new records since 1915 in the four ecoregions that cover nGSL shrimp stocks (Figure 15). The area of the seabed covered by waters with a temperature greater than $6^{\circ} \mathrm{C}$ has increased throughout the nGSL. Part of the bottom area along the Anticosti and Esquiman channels has even been covered by waters warmer than $7^{\circ} \mathrm{C}$ since 2020 (Figure 16). Before 2009, bottom temperatures in these channels ranged from $5^{\circ} \mathrm{C}$ to $6^{\circ} \mathrm{C}$.

The cold intermediate layer was much warmer in August 2021 than in August 2020, reaching the warmest values in modern CTD data. Surface water temperatures were near normal in JulyAugust.
At 200 and 250 m, the Anticosti and Esquiman stocks are found in warmer waters than the Sept-Iles and Estuary stocks. On the other hand, at 150 m , the opposite is observed, the waters are colder in Anticosti and Esquiman since the cold intermediate layer (CIL) is colder in these regions compared to Sept-lles and Estuary.
In recent years, deep water warming and dissolved oxygen depletion have had effects on shrimp distribution. Temperature and dissolved oxygen conditions on the seabed have changed over the last 15 years, with the magnitude of this trend varying from one area to another (Table 2, Figure 17 and Figure 18). During the 2018-2021 period, the range of depths occupied by shrimp decreased in the Estuary, Sept-lles and Anticosti. These changes suggest a movement of shrimp from warmer, oxygen-poor bottoms to colder, oxygenated water layers, but always in association with the bottom to avoid unfavorable environmental conditions. As example, in the Estuary, from 2008 to 2017 , warming (from $2.5^{\circ} \mathrm{C}$ to $4.2^{\circ} \mathrm{C}$ ) and a decrease in dissolved oxygen (from $50 \%$ to $37 \%$ ) occurred in the waters in which female shrimp used to be found, specifically at depths of between 110 m and 320 m . Beginning in 2018, a significant shift of shrimp to new depths was observed. They are now found closer to the CIL at depths of between 70 m and 170 m , in colder $\left(1.4^{\circ} \mathrm{C}\right.$ to $\left.4.0^{\circ} \mathrm{C}\right)$, more oxygenated ( $40 \%$ to $80 \%$ ) waters. The changes in depth have been less dramatic in Sept-lles and Anticosti, where shrimp that used to be found at greater depths are also moving to shallower depths. The median depth of distribution has decreased by roughly 15 m to 20 m as the environmental conditions in which the shrimp find themselves continue to warm and deplete in oxygen in both area. Over a period of 15 years, the median temperature has increased by about $1.0^{\circ} \mathrm{C}$, to over $6.0^{\circ} \mathrm{C}$, and the dissolved oxygen saturation level has decreased from 30\% to 23\% in Sept-lles and from 43\% to 25\% in Anticosti. Warming and declining oxygen levels have also been observed in Esquiman. Since 2008, the water temperature has risen from $5.1^{\circ} \mathrm{C}$ to $6.7^{\circ} \mathrm{C}$ in the areas used by females, and the dissolved oxygen saturation level has decreased from $38 \%$ to $27 \%$. Despite these changes, no
migration of concentrations of shrimp to shallower depths has been observed in this area, and the depth occupied by shrimp has not changed.

As the deep waters travel between the mouth of the Laurentian Channel and its head (located in the Estuary), in situ respiration and oxidation of organic matter cause a decrease in dissolved oxygen. Therefore, the lowest levels of dissolved oxygen are found in the bottom waters of the Estuary. In 2020, concentrations of dissolved oxygen at 300 m were again well below normal everywhere along the Laurentian Channel, reaching time-series record lows in the Estuary and at Rimouski station (Blais et al. 2021). Oxygen saturation has decreased to less than $15 \%$ and water temperatures have increased by nearly $1^{\circ} \mathrm{C}$. Although northern shrimp is particularly well adapted to withstand hypoxia, female shrimp are less tolerant than male shrimp. At $5^{\circ} \mathrm{C}$, the lethal threshold is $9 \%$ saturation for males and $15 \%$ saturation for females (Dupont-Prinet et al. 2013). It should be noted that both sexes of shrimp become more sensitive to hypoxia as temperatures increase; at $8^{\circ} \mathrm{C}$, the lethal threshold is $14 \%$ and $22 \%$ saturation for males and females, respectively (Dupont-Prinet et al. 2013). In addition to being able to tolerate severe hypoxia, shrimp can adapt to oxygen levels that remain chronically near the lethal threshold (Dupont-Prinet et al. 2013; Pillet et al. 2016). Part of the Sept-lles, Anticosti and Esquiman populations therefore live in conditions approaching lethal thresholds.

Recent studies have shown that oxygen depletion and warming of deep waters could result in a loss of habitat for northern shrimp (Stortini et al. 2016). It is expected that deep-water temperatures in the GSL will remain high in the coming years. These conditions are not favourable to northern shrimp, given that it is a cold-water species.

## RECRUITMENT

Environmental conditions affect northern shrimp recruitment from the larval stage until juveniles settle on the bottom. For the Sept-Iles, Anticosti and Esquiman stocks, Brosset et al. (2018) showed that from 2001 to 2016 northern shrimp recruitment appeared to be linked to phytoplankton bloom characteristics and the associated zooplankton phenology, as well as to northern shrimp abundance, rather than to fish predator biomass. It is important to note that the significant variables explaining recruitment were stock-specific and depended on the area considered. The Esquiman area might show increasing northern shrimp recruitment in the future under moderate warming, but recruitment in the Sept-Iles area might be adversely affected. These findings provide a better understanding of stock-specific recruitment in a changing environment and can ultimately improve management of northern shrimp in the GSL. This model had been updated by adding the 2017 and 2018 data during the last assessment and the results are presented in Figure 19. This model could not be updated for the present assessment because some variables were not available because the 2020 spring AZMP survey could not be carried out due to the context of the Covid-19 pandemic.

## COMMERCIAL FISHERY

## FISHERY STATISTICS

The shrimp fishing licence holders have to describe their fishing operations in a logbook. Information on the estimated catch, the number of hours of trawling, and the location of the fishing tows are noted for each day at sea. The catch data are validated with the processing plant purchase slips or with the dock side monitoring program. The dock side monitoring program has been running since 1991; all fishermen have to have their landings weighted by observers who are based in designated ports.

The resolution of the information noted in the logbook and recorded in a zonal file (ZIFF, Zonal Interchange File Format) corresponds to one fishing day at a given location. Every day, the fisherman has to note the total of the estimated catches and the total of hours of trawling for each location. The official landing (coming from the dock side weighting), that happens often after many days at sea, is then attributed proportionally to the daily catches.
DFO official statistics on landings by fishing area are derived from the Canadian Atlantic Quota Report (CAQR) and are available in the Gulf Quota Report.

Northern shrimp landings in the Estuary and Gulf of St. Lawrence have risen gradually since the fishery began. Landings increased from about 1,000 t in the early 1970s to more than 35,000 t by the end of 2010 (Figure 20). Landings decreased thereafter to $17,217 \mathrm{t}$ in 2021. The preliminary statistics indicate 2021 landings of 607 t in the Estuary, 4,907 t in Sept-Iles, 6,205 t in Anticosti, and 5,498 t in Esquiman (Figure 21).
In 2020, the TACs were increased by $154 \%$ in Estuary, by $20 \%$ in Sept-lles and decreased by $8 \%$ in Anticosti and remained the same in Esquiman (Table 3). Those TACs had been set for 2 years of management, i.e. 2020 and 2021. As of January 6, 2022, the TAC has been reached at $100 \%$ in Estuary, at $96 \%$ in Sept-Iles, at $98 \%$ in Anticosti and at $92 \%$ in Esquiman, those data are considered preliminary.

In 2020 and 2021, there was almost no fishing effort in the spring due to the context of the Covid-19 pandemic and the market context. Normally, the proportion of fishing effort between the spring, summer and fall seasons seems consistent over the years (Figure 22).

## DISTRIBUTION OF FISHING EFFORT

The harvest site position that the fisher notes in the logbook is used to identify the shrimp fishing area in which fishing operations are conducted. Depending on the type of form issued to the fisher's fleet, the position is expressed either as latitude and longitude or by identifying the fishing square (a square measuring 10 minutes by 10 minutes, Figure 23). The harvest site may, on occasion, be missing. In such a case, it possible to identify the shrimp fishing area by NAFO subdivision of (Figure 24) find in the logbook.
The spatial distributions of catches, effort and catch per unit of effort (CPUE) by grid square are shown in Figure 25 to Figure 27. They are shown by decade and grid square mean, or for 2018 to 2021.

Use of the Vessel Monitoring System (VMS) has been a license condition since 2012. During shrimp fishing trips, vessels were positioned by satellite at a 60 -minute frequency and, since 2016, every 30 minutes. The information collected consisted of the vessel number (CFVN), position (latitude and longitude), date and time. There is no information on whether a vessel was in a shrimp fishing situation or when the trawl was set. In order to distinguish non-directed shrimp fishery activities, we compared the dates and CFVN in the VMS data with the logbook data. We retained all positions that more or less corresponded to a day when a shrimp catch was recorded in logbooks. It was impossible for another directed-species activity to be conducted in that time interval. Next, we eliminated positions that a vessel travelled through towards the harvest site, and positions where a vessel was stationary (at sea or dockside). To accomplish this, we calculated vessel speed starting from the positions and the time interval between two positions. We retained speeds between 1.8 and 2.6 knots as shrimp trawling speeds and validated this information with fishers. Shrimp fishing positions were aggregated annually in grid squares of 1 minute longitude by 1 minute latitude for charting. With this methodology, the fishing effort retained with the VMS data, i.e. when the shrimpers are fishing,
corresponds to more than $95 \%$ of the total fishing effort declared by the fishermen in their logbook.

The use of fishing activity positions in logbooks (Figure 28) and the VMS (Figure 29) helped delineate fishing activities in the GSL. The sectors that sustain fishing in the 4 areas have barely changed in recent years and correspond to the spots where high concentrations of shrimp were observed during the research survey. In recent years, certain traditional fishing grounds have been abandoned because of the low abundance of shrimp: for example, the area east of the Manicouagan Peninsula in the Estuary, the northeastern tip of the Gaspé Peninsula, the southeast of Anticosti Island, and the southwest of the Esquiman Channel.

## CATCH AND FISHING EFFORT COMPILATION

An observation given by fishermen in their logbook corresponds to a catch and an effort realised by a vessel for a fishing day in a given location. A first validation of the observations is done in eliminating missing or improbable data for essential variables (fishing vessel, catch, effort, date of the catch, shrimp fishing area). Following the validation, the sum of catches does not represent the total of the landings given that some observations had to be removed from the analyses because they were missing or incomplete. The sum of the effort corresponding to the same observations neither represents the total effort put by the fleets to catch the total landing. However, it is possible to estimate the total fishing effort corresponding to the total landing by using the catch per unit of effort estimated from the validated observation subset (Table 4, Figure 30). Similarly, it is possible to estimate the monthly catch and effort by fishing area and by year (Table 5 and Table 6).
The total annual fishing effort of shrimpers has decreased in recent years, from more than 100,000 fishing hours to less than 80,000 hours since 2018 (Figure 31). The effort of the last two years ( 69,400 and 75,400 hours) is below the historical average of 108,900 hours and corresponds to the lowest annual fishing effort observed since 1982. The decrease in fishing effort is noticeable in the four fishing areas, but the scope is greater in the Estuary and Sept-Iles areas.

## CATCH PER UNIT OF EFFORT STANDARDIZATION

The annual catches per unit of effort (CPUE) are standardized to take into account the changes in the fishing capacity and in the seasonal fishing patterns (Gavaris 1980). Multiple linear regressions were performed between the logarithm of CPUE and the variables vessel length and propulsion power (to reflect changes in fishing power), month (to take account changes in the fishing season) and year (to isolate the annual effect without any effect from the other variables). The analyses were performed with the GLM procedure of the SAS software (SAS 1996). The analyses were done separately for each fishing area.

The important variables were first examined to determine if the number of observations in each category was sufficient to be representative of the fleet behaviour. The length and the propulsion power of the vessels were grouped into classes. The lengths were grouped into 6 classes of 10 feet, from 30 to 89 feet, identified by the middle of the class. The powers were grouped into 9 classes of 100 hp , from 100 to 999 hp , identified also by the middle of the class. Given that one observation corresponds to one (or less) fishing day, it is considered that the fishing effort in a given category is representative when many observations (and thus many fishing days) are associated with it.

The conditions for which the fishing effort is considered representative have already been presented in Savard (2011). They are the following:

- a vessel had to be active during at least 3 years and had to have at least 7 observations per year;
- a length or power class had to be present during at least 3 years and had to have at least 7 observations per year;
- the months that were kept were those during which there were activities for at least 3 years and for which there are at least 7 observations ( 5 observations for the Estuary area) per year and per fishing area;
- an observation would be considered as significant if it corresponds to an effort greater than one hour and a catch greater than 50 kg ;
- the sub-categories representing less than $1 \%$ of the total observations were not used in the analyses because it was considered that they were little representative of the behaviour of the fleets.
The validation of these models is done by analyzing the residuals against the predicted values and categories of factors studied. The analyses of variance are all significant ( $p<0.0001$ ) as well as the contribution of the categories to the regression ( $p<0.0001$ ) except for the length category ( $\mathrm{p}=0.0120$ ) in the Estuary area. The model explains $53 \%$ of the variance in Estuary, $51 \%$ in Sept-lles, 58\% in Anticosti and 58\% in Esquiman.
The standardized CPUEs correspond to a standard vessel with a length class of 60-69 ft and a propulsion power class of 500-599 hp and the month is June. CPUE values have varied widely over time and have followed similar trends since 1982 in all four fishing areas. CPUEs were low from 1983 to 1995; they began increasing in 1995 and peaked around 2005, after which they remained high for a few more years (Table 7 and Figure 32). From 2014 to 2017, CPUEs decreased. In 2020 and 2021, CPUEs improved in the Estuary, Sept-lles and Anticosti compared to 2018 and 2019, while those in Esquiman have been more variable over the past four years. The CPUEs of the four areas are comparable to those observed in the early 2000s and higher than those observed in the early 1990s.

## COMMERCIAL CATCH SAMPLING

Samples from commercial catches have been collected at landing since 1982 (Table 8). The samples are brought back to the laboratory where the individuals are sexed and measured (cephalothorax length, CL) to the closest 0.1 mm . The individuals are sexed according to the characteristic of the endopod of the first pleopod (Rasmussen 1953) and the maturity stage is determined by the presence or absence of sternal spines (McCrary 1971) and by the presence or absence of eggs.

Commercial catch samples are combined by area and by month. The monthly length frequency distributions are weighted by the month landing (Table 9) and the numbers at length are calculated by applying the weight-length relationships estimated from the survey (see section DFO research survey). The annual commercial catches are estimated by summing the monthly numbers at length (Table 10). The numbers per unit of effort are calculated by dividing the numbers at length by the fishing effort (Figure 33 and Figure 34).

The main indicator of the stock status is estimated using data from the commercial fishery and research survey. Indices used from commercial fishing are numbers per unit of effort (NPUE) during the summer for the male and female components. These indices have been restricted to the summer (June, July and August) due to seasonal variations in catchability. The male and female NPUE are estimated from length frequency of summer months by fishing area (Table 11 and Figure 35).

Mean lengths of female carapace shrimps harvested in the summer by fishing area and year are presented in Figure 36. The general trend in the four areas indicates that the female shrimp caught are getting smaller and smaller over the years. The average lengths of 2021 are all smaller than those of 2020.

## DFO RESEARCH SURVEY

## DESCRIPTION OF THE SURVEY

A ecosystemic research survey has been conducted annually in the nGSL since 1990 to estimate the abundance of northern shrimp and groundfish species. The survey is conducted with a shrimp trawl following a stratified random sampling plan. Fishing operations take place 24 hours a day. A description of the 2021 survey and sampling protocols is presented in Bourdages et al. (2022).

The stratification used for the allocation of fishing stations is presented in Figure 37. In the Gulf, the grounds located at depths greater than 37 m ( 20 fathoms) are covered by the survey (with the exception of the Mecatina Trough). In the Estuary, the survey covered the grounds at depths greater than 183 m (100 fathoms) from 1990 to 2007. In 2008, it was decided to add strata to cover depths from 37 to 183 m in this sector to obtain a better coverage of the northern shrimp spatial distribution. The surface of the study area has increased from $116,115 \mathrm{~km}^{2}$ to $118,391 \mathrm{~km}^{2}$.

In 2021, 149 fishing stations were successfully sampled, specifically 41 in 4R, 69 in 4 S and 39 in 4T, which represent 40 stations less than what has been achieved on average since 1990 (Table 12, Figure 38). The decrease in the number of stations completed is due to the fact that the ship had to go to the wharf three times for medical or mechanical reasons. A lot of effort was made to cover the entire study area. Six strata were not sampled with a minimum of two stations, two of which were not visited. These partially or uncovered strata were distributed throughout the study area and not located in a particular sector.
For each fishing tow, the trawl catch is sorted by species or by taxon. The total catch of shrimp is weighted and a sample of about 2 kg is collected to determine the proportion of Pandalus borealis compared to other shrimp species and its biological characteristics as well. The maturity stage (male, primiparous or mutiparous female with or without gonads in maturation and egg bearing female) is identified for each individual. The cephalothorax length is measured with an electronic calliper with a precision of 0.1 mm . The individual weight is recorded with a precision of 0.1 g following a stratified sampling design (about ten individuals per sex per 1 mm length class) for each fishing area. In 2020 and 2021, surveys were carried out with a reduced number of scientific personnel in order to comply with working protocols at sea in the context of the Covid-19 pandemic. The shrimp samples were therefore frozen and processed in the laboratory in the fall. Only the individual weights could not be made in the laboratory following the freezing of the samples because the weight following thawing is not comparable to the fresh weight.
The area swept by the trawl is estimated from the duration of the tow, the speed of the vessel and the wingspread of the trawl. The $P$. borealis catch for each tow is estimated from its proportion in the sample and is standardized to an area of $1 \mathrm{~km}^{2}$ taking into account the swept surface (Table 13 and Figure 39).

## DISTRIBUTION

## Geographic distribution of catches

The geographical distribution of catches by weight per tow ( $\mathrm{kg} / 15$ minutes tow) was made for periods of four or five years (Figure 40). The interpolation of catches was performed on a grid covering the study area using a ponderation inversely proportional to the distance ( R version 2.13.0, Rgeos library; R Development Core Team 2011). The isoline contours were then plotted for four biomass levels which approximate the $20^{\text {th }}, 40^{\text {th }}, 60^{\text {th }}$ and $80^{\text {th }}$ percentiles of the non-zero values. The catch rates distribution of males and females from 2018 to 2021 are also presented in a bubbles type map (Figure 41).

The survey is deemed to effectively cover the entire distribution range of northern shrimp in the nGSL. The spatial distribution of northern shrimp shows that the best catch rates were observed along the Esquiman, Anticosti, and Laurentian channels, as well as west of Anticosti Island through the Estuary. Typically, young shrimp are found in shallower areas, often at the heads of channels, whereas older individuals, females, are found in deeper waters. Northern shrimp occurs only rarely in the southern Gulf.

## Distribution of catches by depth, temperature and dissolved oxygen

The relative cumulative frequency of catches (in weight) was compiled according to depth, temperature and dissolved oxygen for the periods 1995-2010 and 2018-2021 (Figure 42). This relationship was depicted in graph form, in combination with the relative cumulative frequency of the number of stations sampled by depth in the study area. This figure illustrates the depth windows in which the shrimp is likely to be caught in August in the study area.
Research survey data indicated that from 1995 to 2010 more than $80 \%$ of the cumulative northern shrimp biomass was found between 190 and 331 m at bottom temperatures ranging between 4.0 and $5.9^{\circ} \mathrm{C}$ and oxygen concentrations dissolved between 24 and $48 \%$. With the warming of deep water temperatures in recent years, we observe that shrimp are now found at shallower depths. From 2018 to 2021, more than $80 \%$ of the cumulative biomass was found between 164 and 302 m at bottom temperatures varying between 3.0 and $6.4^{\circ} \mathrm{C}$ and dissolved oxygen concentrations between 20 and $48 \%$. In general, the northern shrimp is associated with the deep water mass and is found mainly in channels at depths ranging from 200 to 300 m where the sediments are fine and consolidated (Dutil et al. 2011).

## Area of occupancy

Three spatial indices were selected: the design-weighted area of occupancy, the D95 and the Gini index.

Design-weighted area of occupancy
The design-weighted area of occupancy (DWAO) (Smedbol et al. 2002) is the area of the study zone in which the shrimp is found.

## D95

The D95 index describes geographic concentration. This descriptor corresponds to the minimum area containing $95 \%$ of the shrimp biomass. Calculation details are described in Swain and Sinclair (1994).

## Gini index

The Gini index quantifies the homogeneity of shrimp distribution. This index is calculated using the Lorenz curve (Myers and Cadigan 1995). The index goes from 0 to 1 , where 0 corresponds to a perfectly homogenous distribution and 1 corresponds to a very concentrated distribution.

In 2021, northern shrimp was distributed over more than 90,000 $\mathrm{km}^{2}$ in the nGSL, the study area was $116,115 \mathrm{~km}^{2}$ (Table 14, Figure 43 and Figure 44). Since 2008, the northern shrimp has been increasingly concentrated (increase in the Gini index) and there is a decrease in the area where the highest concentrations of shrimp are observed, i.e. the area where more than $95 \%$ of the biomass is distributed. Since 2010, the minimum area (D95) has fallen from more than $50,000 \mathrm{~km}^{2}$ to less than $30,000 \mathrm{~km}^{2}$, i.e. a decrease of almost $50 \%$ in the area occupied by the population.

## BIOMASS ESTIMATION BY GEOSTATISTICS

The biomass (kg/km²) calculated at all stations of the study area is kriged separately for males and females. First, the positions of sampling stations, expressed in latitude and longitude, are transformed into a Cartesian coordinate system according to the Lambert Conformal Conic projection using parallels $48^{\circ} \mathrm{N}$ and $50^{\circ} \mathrm{N}$ as a reference and $46.5^{\circ} \mathrm{N}$ and $70^{\circ} \mathrm{O}$ as point of origin. This conversion is carried out using libraries "sp" and "rgdal" (2013a Pebesma, Bivand 2013) of R (R Development Core Team 2008).
As a first step, a variogram is calculated for each survey. To highlight the spatial structure of the data, it is sometimes necessary to remove outliers. The values of cuts are shown in the Table 15. Likewise, values lower than $5 \mathrm{~kg} / \mathrm{km}^{2}$ are not used for estimating the variogram. From 1990 to 2012, annual variograms were estimated with the procedure "VARIO" of SAS software (SAS 1996). From 2013, the variograms were performed with the library "gstat" of $R$ (Pebesma 2013b). The semivariances were calculated between all pairs of stations. The distance (h) between them was discrete and semivariances were averaged for different distance classes with intervals of 15 km and a maximum distance of 225 km .

In a second step, the annual variogram is standardized, that is to say that semivariances are divided by the observed variance of the data used to construct the variogram. Subsequently, a pluriannual variogram is constructed from the average of the last three variograms, that of the current year and the two preceding years. The pluriannual variogram corresponds to the mean of the semivariances for each distance $h$ of the annual variograms, weighted by the number of pairs associated with these distances. The use of a pluriannual variogram reduces the variability of the spatial structure which is observed in some years, allowing a better fit of the model.
From 1990 to 2012, the various parameters of the multi-year variograms (the nugget, the sill and the range) were set manually in order to obtain the best possible fit (Table 16). Although other variogram models were examined, the exponential model was selected because it produced the best fit. Since 2013, the parameters of the exponential variogram were fitted with the function "fit.variogram" from the library "gstat" of R (Pebesma 2013a). To minimize the least squares, the adjustment was performed by weighting the data by $N_{j} / h_{j}^{2}$ order to give more weight to the adjustment of the first points of the variogram (Figure 45).
Thereafter, the values of catches were spatially interpolated in the study area using kriging. To do this, all survey observations were used including low and extreme values. The pluriannual variogram was adjusted to represent the variance of the observations of the study area. The nugget $\left(\mathrm{C}_{0}\right)$ and sill parameters (C) were multiplied by the variance of all observations in the study area. The interpolation was performed on a regular grid with nodes separated by
distances of 5 km in both directions. The local estimations were made using the catches of the eight nearest stations that are present within a maximum search radius of 200 km .
From 1990 to 2012, the kriging, the estimates of the mean and variance estimation were performed using the toolbox "Kriging" of MATLAB (Lafleur and Gratton 1998). Since 2013, the kriging was performed with the function "krige" of the library "gstat" of R (Pebesma 2013a) and the estimates of the kriging mean and variance estimation were calculated using a function developed by Sébastien Durand (pers. comm.).

The mean biomass $\left(\mathrm{kg} / \mathrm{km}^{2}\right)$ of each fishing area is then calculated by doing the mean of the local estimations in the area. The total biomass of a given fishing area is obtained by multiplying the mean biomass by the surface of the area. The surfaces of the fishing areas are as followed: Estuary, 4,000 km² from 1990 to 2007 and 6,325 km² from 2008 to 2017; Sept-lles, 29,775 km² from 1990 to 2007 and 29,975 km² from 2008 to 2017; Anticosti, 46,400 km²; Esquiman, $32,350 \mathrm{~km}^{2}$.

Maps of total biomass distribution are shown for each year in Figure 46 and maps of the distribution of male and female shrimp are shown in Figure 47 and Figure 48. Indices of total biomass (Figure 49) and of male and female biomass (Figure 50, Table 17 and Table 20) in the Sept-Iles, Anticosti and Esquiman areas showed upward trends in the1990s, but declining trends have been observed since 2003. The biomass observed since 2017 are comparable to the low values of the early 1990s. For the Estuary zone, the interannual variations are large, the biomass observed in 2020 and 2021 are among the lowest in the chronological series while the estimate for 2019 was among the highest.

Biomass estimates are generally more accurate for females than for males. The coefficient of variation is approximately $20 \%$ to $30 \%$ for males and $10 \%$ to $20 \%$ for females in the Sept-lles, Anticosti and Esquiman fishing areas (Table 18 and Table 19). The coefficient of variation is higher in the Estuary.

## ABUNDANCE ESTIMATION

Biomasses estimated by kriging are converted into abundance from the weight-length relationships and from the length frequency distributions. Length frequencies of each sample are first bumped to the total catch of the station and then, standardized to a $1 \mathrm{~km}^{2}$ swept area. The frequencies ( $\mathrm{n} / \mathrm{km}^{2}$ ) are regrouped into 0.5 mm size class.

The mean distribution of frequencies (in $\mathrm{n} / \mathrm{km}^{2}$ ) per size class is estimated for each fishing area, for males and females. The mean distribution is estimated from all stations that were sampled in the fishing area. The mean distribution is then converted into weight by applying a weight-length relationship that is estimated for each area (Table 21, Figure 51). The weight-length relationship estimated in 1993 is used for the 1990-2004 period. Since 2005, the relationship estimated annually is used for the current year. The same relationship is used for both sexes. In 2020 and 2021, there was no biological measurement on individual shrimps, so the relationship estimated in 2019 was applied to these missing years.
The stock biomass estimated by kriging is distributed among the size classes following the proportions in weight of the mean distribution of the stock. The abundance of each size class is obtained by dividing the biomass by the mean weight of the class. The total stock abundance is then obtained by adding the abundance of all size classes. The exercise is done separately for males and females. Given that the numbers are not kriged, it is not possible to obtain an estimate of the variance of the abundance by kriging. Therefore, the coefficient of variation of the biomass is used to estimate the $95 \%$ confidence interval of the abundance.

The female abundance could be separated into maturity stages for the years when the identification of the stage was done for each individual. The abundance of primiparous and multiparous females was calculated from 1990 to 2000 and then from 2009 to 2021.

The population structures for each fishing area derived from the DFO survey are presented for males and females in Figure 52 and Figure 53. In 2021, the abundance of small males is very low in the four areas, while the largest males are above the average for the series in the Estuary and below the average in the other three areas. The abundances of females are very low in Sept-Iles, Anticosti and Esquiman, while in Estuary, they are above average whereas they were below average in 2020.

It is possible to obtain an index of recruitment by estimating the abundance of juveniles for which the cephalothorax length is smaller than 12.5 mm . The individuals of these sizes are aged of about fifteen months (Daoud et al. 2010). The estimation of abundance of the juveniles is obtained by adding the abundance of the size classes that are included in the first mode. In 2021, the abundance of juveniles (carapace length between 8 and 12 mm ) was very low in the four areas. In 2020, recruitment was also very low in areas with the exception of Anticosti where it was average (Figure 54, Table 23).

After showing downward trends for more than ten years, the abundance indices for males and females in the Sept-Iles, Anticosti and Esquiman areas seem to have stabilized at very low values since 2017 (Table 22 and Figure 55). The 2021 abundances for these three stocks are low compared to the values observed between the years 2000 and 2010. The values for Septlles and Anticosti are compared to the lowest values observed in the early 1990s. The abundance indices for males and females in the Estuary, for the surface covered by the survey since 1990, are very low in 2020 and 2021 whereas they were high in 2019. When looking at the estimates coming from the surface enlarges with the shallower strata in 2008, the 2021 male and female estimates are high compared to the low values observed in 2020.

The allocation of additional stations in the shallow area of the St. Lawrence Estuary since 2008 has had a very significant impact on the number of males and females surveyed in the Estuary fishing area and to a lesser extent in the Sept-lles area (Figure 55). After 14 surveys with this increased coverage, the inter-annual coherence between the shrimp abundance measured according to the original area and the extended survey area indicates that the biomass was largely underestimated and the exploitation rate index significantly overestimated for the Estuary area. In the short term, shallow strata should be integrated into estimates of the main indicator of stock status.

The variations in shrimp sizes follow an east-west gradient, the smallest being observed in the Esquiman Channel and the largest, in the Estuary. In all four areas, the average size of male and female shrimp showed a downward trend over the 1990-2021 time series. In 2021, the average size of males and females in the Estuary, Anticosti and females in Esquiman were larger than the sizes recorded in 2020 (Figure 56). The survey has collected individual weight data since 2006. Shrimp weight estimates for males of 14 and 20 mm and females of 22 and 26 mm seem to increase over the years (Figure 57). The weight of the shrimp was higher than average in the Esquiman and Anticosti areas from 2010 to 2018, and has been higher in the Sept-Iles area since 2012 and in the Estuary since 2015, following a gradient that began earlier in the east. These indices were not estimated in 2020 and 2021.

## PRECAUTIONARY APPROACH

The precautionary approach (PA) for northern shrimp in the GSL was adopted in 2012 in accordance with the fishery decision-making framework incorporating the precautionary approach (DFO 2006).

## MAIN STOCK STATUS INDICATOR AND REFERENCE POINTS

The stock assessment is descriptive and focuses on the review of indices from the commercial fishery and research survey. These two sources of data are independent and allow the estimation of catch rates or densities which are considered as good indices of shrimp abundance. During the PA development, it was decided to use them both equally (with the same weight) in the constitution of the main indicator of the stock status (Savard 2012). However, given the seasonal variations in catchability the estimation of the fishery indicators is restricted to summer (in June, July and August), the season during which catchability for males and females is considered constant.

Given that the northern shrimp changes sex, it is important to protect at the same time the male (recruitment to the female component) and the female components (spawning stock) of the stocks. Although no specific study was realized, we assume that the abundance of males is not a factor limiting the success of reproduction. The proportion of reproductive females carrying fertilized eggs early in spring before the hatching of larvae had always been very high (98\% or more in the Sept-Iles area since 1992). However, the number of recruit females (primiparous) in a given year depends on the number of males which undertook the process of sex change in the previous winter. The abundance of primiparous females is directly proportional to the abundance of all males of the previous year.
Also, the abundance of the reproductive females in spring can be predicted from the estimation of the spawning stock of the previous summer. The spawning stock estimated in summer consists of primiparous females which have completed the sex change and of multiparous females which survive the reproduction and the release of larvae.
Male and female abundance indices are calculated from indices for each sex obtained from the fishery in summer (number per unit of effort in June, July, and August) and from the research survey (abundance). The combination of these indices constitutes the main indicator of the stock status. To be able to combine them, each index is first standardized to a period of reference (1990-1999, except for Estuary 1995-1999). The main indicator of stock status is the average of the four standardized indices. For the Estuary, the survey indices are based on the sampling area covered since 1990, specifically the four strata corresponding to depths greater 183 m .
Like the main stock status indicator, the limit reference point (LRP) and the upper stock reference point (USR) were developed in fall 2011 (Savard 2012; DFO 2011).
Stocks increased from a relatively low abundance level in the mid-1980s and mid-1990s due to the production of abundant year-classes. During the 1980s, predator abundance was high and likely had a major impact on the maximum abundance level reached by the stocks. In the 1990s, abundant cohorts were produced at a time when predator abundance was declining. It appears that the spawning stock was large enough to produce abundant cohorts, which had a noticeable effect on stock condition. Stock status corresponding to these low abundance levels, which have since increased, represents the limit reference point (LRP). The stocks' behaviour in the critical zone is uncertain, however, because such a situation has never been observed during the period under study.

The production of very abundant year-classes allowed stocks to begin increasing again in the early 2000s when predation mortality was likely low. However, stock status has been declining since 2003 and exploitation rate indices have been increasing. It is therefore uncertain whether the abundance levels observed since 2003 can be maintained. The 1996 to 2002 period appears to have been a stable period characterized by sustainable catch levels. The average stock status for this productive and stable period represents a biomass approximation based on the maximum sustainable yield. The value of the upper stock reference (USR) point was set to $80 \%$ of the mean value of the indicator for the 1996 to 2002 period. The values assigned to the limit reference point and the upper stock reference point, in keeping with the fishery decisionmaking framework incorporating the precautionary approach, are presented in the Table 24.

The standardized abundance indices for male and female shrimp derived from the fishery and the research survey show similar trends for the Sept-lles, Anticosti and Esquiman stocks since the 1980s to 2005. The indices were low in the 1980s and the early 1990s (Table 25 and Figure 58). The indices showed an upward trend from the mid-1990s until 2003. Commercial fishery indices remained fairly stable and high in subsequent years, whereas the survey indices began to decline. Fishery indices began to decrease in 2015. In 2021, we observe very low abundance indices while the fishery indices are average. The Estuary area indices are much more variable from one year to the next. The abundance indices are low in 2020 and 2021 while they are high in the fishery.

In 2021, the main stock status indicator decreased slightly in all four areas. The indicators of the four areas are very close to the upper reference point. The Estuary, Anticosti and Esquiman stocks are in the healthy zone, while the Sept-lles stock is still in the cautious zone (Figure 59). Even though the Sept-Iles stock indicator has improved compared to 2018, this stock remains in the cautious zone for a fifth consecutive year.

When the PA was developed in the early 2010s, the commercial catch rate and the research survey abundance index were relatively consistent. From 1993 to 2005, the stocks were growing and the fishery and survey indices followed the same trend. From 2005 onward, the research survey index began to decline, while the commercial catch rate remained stable at relatively high levels. The fishery indices began to decline in 2015, ten years after those of the scientific survey. This time lag is consistent with the dynamics observed for other exploited species, where harvesting is focusing on areas of high concentration after an effective search for these areas has been conducted. The pattern observed in the NPUEs is described as "hyperstability," or a maintenance of commercial catch NPUEs as the population abundance declines (Harley et al. 2001; Walters 2003). The two indices are therefore not sampling the same fraction of the population. The research survey covers the shrimp's entire range in the Estuary and northern Gulf of St. Lawrence, while the commercial fishery targets the highest concentrations of shrimp at the channel heads.
Technological developments in the fishery, such as the use of seabed mapping, echo sounding and new trawls, have improved fish harvesters' efficiency. This means that, given the same abundance, a recent NPUE will be greater than an older NPUE. As a result, the comparison of these NPUEs in a historical series will be skewed.
The area of occupied shrimp habitat is shrinking every year. As their habitat becomes increasingly concentrated in a smaller and smaller area, shrimp are becoming more vulnerable to fishing. Today, given the same abundance, shrimp are more densely concentrated on the seabed.

If the goal is to have an indicator to monitor population trends, these factors indicate that the use of commercial fishery NPUEs has overestimated stock abundance during the most recent period of decline.

The average size of male and female shrimp has been declining in all four stocks since the early 1990s. This trend can be observed in both the commercial fishery data (Figure 36) and the DFO research survey data (Figure 56). For populations of similar abundance, a decrease in the average size of individuals will have a negative impact on the stock's reproductive potential since fewer eggs will be produced per female (Parsons and Tucker 1986). The main stock status indicator is calculated from indices based on number of shrimp, which are related to harvests expressed in weight. Continuing to use a decision rule based on this relation could increase the rate at which the spawning component of the stock is exploited
For these reasons, the main stock status indicator is considered overestimated for the most recent period

## HARVEST GUIDELINES AND DECISION RULES

Harvest guidelines were established according to the main indicator and its position in relation to the stock status classification zones (healthy, cautious and critical) in accordance with the precautionary approach. These guidelines were established based on the historical relationship observed between the main stock status indicator for a given year and the following year's harvest level. This relationship was modified based on the stock status zones to adjust the exploitation rate according to the status of the resource. The exploitation rate is constant when the stock is in the healthy zone; the value used is equal to the mean rate observed between 1990 and 2010. The harvest rate decreases through the cautious zone to the critical zone, where the exploitation rate is set a constant value that is four times lower than that for the healthy zone. The guidelines for the four fishing areas are presented in the Table 26.
A simulation model was developed to test these guidelines and compare the performance of various harvest adjustment rules (Desgagnés and Savard 2012; Bourdages and Desgagnés 2014). The operational model adapted to the dynamics of a northern shrimp stock successfully captured the evolution of a model population and supported the testing of multiple assumptions concerning stock dynamics. The model can be viewed as a powerful tool for simulating stock trajectory and assessing risks and uncertainties as part of the evaluation of management strategies.
Fisheries Management will set the TACs for the coming year on the basis of the projected harvest levels by applying the decision rules of the current precautionary approach. To minimize TAC adjustments between two consecutive years, decision rules apply a threshold and a cap to TAC adjustments. If the difference between the TAC and the projected harvest level is less than $5 \%$, no adjustment will be made. If the stock is in the healthy zone and the difference between the TAC and the projected harvest level is greater than $5 \%$, a cap will be applied and the TAC adjustment (positive or negative) will not exceed $15 \%$.
The TACs were adjusted annually from 2012 to 2018 in keeping with the precautionary approach, even though northern shrimp in the Estuary and Gulf is managed on a two-year cycle. In 2019, in response to requests from industry and the First Nations, DFO agreed to adopt biennial decision rules, a scenario that was assessed in 2014 and found to meet conservation objectives. The main justification for their request was that redfish predation was having a greater impact than the fishery in terms of causing a decrease in the shrimp population. The TACs were therefore adjusted in 2018 and 2020, following the stock assessment review, and were established for period of 2 years.
According to the guidelines established as part of the precautionary approach, the projected harvest levels for 2022 are 558 t for Estuary, 6,242 t for Sept-lles, 5,424 t for Anticosti and $5,079 \mathrm{t}$ for Esquiman (Figure 60 and Table 27). Fisheries Management will set the TACs for

2022 based on these harvest levels by applying the decision rules of the precautionary approach and the advisory committee findings.

## EXPLOITATION RATE

An exploitation rate index is obtained by dividing the commercial catches in number by the abundance value estimated from the research survey. This method does not allow the absolute exploitation rate to be estimated or the index to be related to target exploitation rates. However, it does permit tracking of relative changes over the years. The exploitation rate in the Estuary is highly variable, as are the abundance indices from the survey, in 2021 it was below average (Figure 61). Exploitation rates in the Sept-Iles, Anticosti and Esquiman areas show an increasing trend since 2005. In 2021, they increased in Sept-l̂les and Anticosti and decreased in Esquiman. In these three areas, the exploitation rate is above the historical average and is among the highest values in their respective series.

## CONDITIONING THE PRECAUTIONARY APPROACH FOR OBSERVED CHANGES IN THE ECOSYSTEM

The GSL northern shrimp PA assumes that the environment varies randomly within the envelope of conditions that prevailed during the time period considered to define the reference points and harvest control rule for each stock (from 1990 to 2010). However, the directional changes observed over the last decade in the GSL ecosystem no longer allow these conditions to be met. The sustained increase in bottom water temperature, the decrease in oxygen in the deep layer, and the significant increase in redfish biomass (predation) indicate that the ecosystem framework within shrimp stocks and their fishing has changed. This deviation from 1990-2010 conditions increases the level of uncertainty in assessing the shrimp stock status, as well as the risks associated with harvests projected by the current PA. Not taking this increased risk into account would be equivalent to deviate from the initial intentions of the PA in terms of caution.

In this context, an adjustment of the degree of exposure of stocks to fishing pressure is proposed. This adjustment consists of formulating a "conditioned" opinion on the observed, anticipated or projected effects of environmental changes on the state of the stocks, so as to maintain an equivalent level of risk (Duplisea et al. 2021; Roux et al. 2022). Various approaches to adjust the degree of exposure of fish stocks to fishing pressure to account for ecosystem changes have emerged in recent years (Dorn and Zador 2020; Bentley et al. 2021; Duplisea et al. 2021 Howell et al. 2021). These approaches can be adapted to the practices and methods in place in order to formulate without delay scientific advice conditioned to better integrate climate, ecosystem or environmental changes. These approaches are applicable regardless of the type of data and knowledge available (i.e. qualitative, semi-quantitative or quantitative data, and experiential, empirical or analytical knowledge).

## Indicator to the state of the environment for northern shrimp in the GSL

Bottom water temperature was selected as an indicator of the state of the environment for northern shrimp. This choice was made in consideration of the following factors:

1. demonstrated effects of water temperature on shrimp productivity (Apollonio et al. 1986; Wieland 2005; Koeller et al. 2009; Richards et al. 2012; Arnberg et al. 2013);
2. the availability of temperature time series covering the reference period considered to define the PA;
3. the depth corresponding to the median value of the shrimp biomass distribution in each fishing area in 2021 ( 150 m in the Estuary and 250 m in the other areas);
4. the positive correlation between bottom water temperature and redfish biomass (predation pressure) in the ecosystem (Pearson's $r$ coefficient $=0.71, p<0.001$ over the period from 1990 to 2019); and
5. the anticipated decrease in oxygen availability with increasing water temperature (Davis 1975).

The evolution of temperature conditions during the reference period (1990-2010) until today (2020-2021), are illustrated for each fishing area in Figure 62. These data confirm that the fishery operates presently outside the environmental conditions that prevailed at the time of defining the PA parameters for the northern shrimp of the GSL.

## Conditioning factors

Conditioning advice for fisheries on the state of the environment consists of mobilizing available knowledge and information in order to determine ecosystem or environmental conditioning factors (ECFs). These factors correspond to the ratio of the 'adjusted' advice for the demonstrated, anticipated or projected effects of changes in the environment, on the 'status quo' advice developed by assuming that the environment is stationary or varies randomly at within the conditions observed over the reference period. Depending on the data and knowledge available, ECFs are determined semi-quantitatively, empirically or analytically (Roux et al. 2022). The difference is in the proportion of uncertainty associated with environmental change that is quantified within the assessment process.

For northern shrimp in the GSL, there is currently no empirical or analytical model to quantify the effects of fishing on stocks, nor an empirical or analytical model of the effects of temperature and other ecosystem conditions (eg predation mortality) on stocks. The sum of the evidence, however, suggests direct negative effects (eg impact on physiology and on the availability of optimal thermal habitat) and indirect (eg increase in natural mortality caused following the increase in the abundance of redfish in response to deep water warming) from the increase in water temperature for shrimp. Under these circumstances, a semi-quantitative conditioning factor, based only on temperature, has been proposed:
$E C F_{i, E, F}=\left(S_{i, E} \times \frac{E_{\text {current }}}{E_{\text {base }}}\right) \times k_{i, E, F}$
This ECF corresponds to the product of the sensitivity of northern shrimp to water temperature (S) and the ratio of current temperatures compared to the average observed during the reference period (Ecurrent/Ebase), multiplied by a parameter d scale (k) expressing the severity of the anticipated consequences of the increase in temperature for fishing. An ECF is calculated for each stock (i), the selected environmental variable (E) (bottom water temperature) and the fishing activity ( F ) subject to the advisory (targeted shrimp fishery).

The sensitivity parameter expresses the response, avoidance and adaptation capacity of the shrimp to temperature changes. The value of S used corresponds to the water temperature sensitivity scores of northern shrimp determined in a climate change vulnerability analysis (Hare et al. 2016; NOAA 2020). These scores, based on expert knowledge, have an average value of 3.2 out of a maximum of 4.0. The variability between the scores of different experts was taken into account by randomly sampling values of $S$ from a uniform distribution with $S_{\text {min }}=2.8$ and $\mathrm{S}_{\max }=4.0$ (which corresponds approximately to the shape of the distribution and the range of sensitivity scores in the study). The median value of $S$ obtained from this sampling was used for each stock in the GSL.

The ratio Ecurrent/Ebase expresses the amplitude of the current deviation of the temperature compared to the reference conditions (state of the environment). The normalized value of the ratio of the average bottom temperature in 2020-21 (Ecurrent) to the average observed in 19902010 (Ebase) in each fishing area is used.

The value of the consequence parameter (k) is currently unknown. An arbitrary value randomly sampled from a uniform distribution between $k_{\min }=0.1$ and $k_{\max }=0.3$ is used. This approach has the effect of constraining the anticipated consequences of the change in temperature on fishing not to exceed $30 \%$ of the product of sensitivity and state of the environment (while remaining greater than or equal to $10 \%$ of this same product). The median value of k (around 0.2 ) is comparable to the arbitrary value of the 'precautionary buffer' used in Europe to adjust fisheries advice when available data and knowledge are limited (ICES 2021). Simulations have shown that lower conditioning (reduction of catches) by $20 \%$ can limit the increase in risk in advice on data-poor stocks (ICES 2017).
The ECFs obtained for each shrimp stock are presented in Table 28. Given the similar values of sensitivity ( S ) and consequence ( $k$ ) used for each stock, there is little contrast in the ECFs between fishing areas. Only the state of the environment (Ecurrent/Ebase) differs more or less pronounced between the stocks. This approach is considered appropriate given the uncertainties relating to the structure of northern shrimp stocks and their degree of spatial connectivity, particularly with regard to recruitment processes (Le Corre et al. 2020).

## Conditioned harvest on the state of the environment

The harvest control rule (HCR) of the PA is used to determine the level of sustainable harvest in year $x+1$ depending on the state of the stock in year $x$. The HCR parameters are therefore an approximation of the response of shrimp stocks to fishing removals, as determined by simulations (Desgagnés and Savard 2012). The conditioned harvest for the state of the environment are obtained by multiplying the parameters of the HCR by the ECF calculated for each stock (Figure 63). The inverse value of the ECF (1-ECF) is used because the increase in water temperature corresponds to unfavorable environmental conditions for northern shrimp.
The result of conditioning is a reduction of harvests of $15 \%$ in Estuary and Sept-lles, and 17\% in Anticosti and Esquiman compared to projected harvest according to the current PA (status quo) (Table 28, Figure 63). This downward adjustment allow to minimize an increase in biological and ecological risks for shrimp stocks in the context of an environment unfavorable to their productivity. In other words, the conditioning serves to maintain a level of safety consistent with the original intentions of the PA.
The ECF calculated for each stock allow to use the knowledge and information available in order to condition the advice on fisheries on the state of the environment. Additional research work (simulations) is needed to inform the value of the consequence parameter ( $k$ ) for northern shrimp, as well as to alleviate the linearity constraint imposed by equation 1 . Such work will increase the robustness of semi-quantitative ECFs proposed to condition fishery advice for GSL northern shrimp stocks.

## IMPACT OF THE FISHERY ON THE ENVIRONMENT

## IMPACT ON HABITAT

The use of the vessel monitoring system (VMS) since 2012 has made it possible to determine the locations of fishing grounds and the trawling footprint on the seabed (Figure 64). Since 2012, total annual fishing effort has amounted to about 82,000 hours, which corresponds to a
maximum annual footprint of approximately $7,000 \mathrm{~km}^{2}$, assuming that the trawl tows do not overlap (Table 29). This effort is concentrated in an area of $23,000 \mathrm{~km}^{2}$ where fishing intensity is variable (Figure 64). The fishing zone with the most intense activity corresponds to an area of $1,300 \mathrm{~km}^{2}$ where $26 \%$ of fishing effort is deployed.
The fishing effort of shrimpers in the Estuary and northern Gulf of St. Lawrence is concentrated and the fishers return to the same fishing grounds year after year. Moritz et al. (2016) suggested that, in this long-exploited ecosystem, a critical level of disturbance was already reached at the time of the first gear passages, which occurred decades ago and had irreversible impacts on the seabed by removing vulnerable taxa and structures providing three-dimensional habitats. These authors also indicated that it is likely that benthic communities subsequently reached a disturbed state of equilibrium on which current trawling has limited or no further impacts.

Fishing effort has declined over the past six years, going from more than 110,000 hours of fishing to fewer than 70,000 hours. This effort has been more concentrated on shrimp holes. The area of the zone in which trawling is carried out has decreased from $15,000 \mathrm{~km}^{2}$ to $10,000 \mathrm{~km}^{2}$. This points to a potential decline in the impact of the fishery on habitat.

Fisheries management measures aimed at conserving corals and sponges in the Estuary and Gulf of St. Lawrence were put in place in 11 areas totalling $8,571 \mathrm{~km}^{2}$ on December 15, 2017. The use of bottom-contact gear, such as the bottom trawls used by shrimpers, is prohibited in these areas. This type of gear poses a risk to these important benthic communities, given that cold-water corals and sponges are fragile biogenic species that recover very slowly. The analysis of VMS data has shown that fishers are respecting these areas: no fishing effort was observed in these zones since 2018 (Figure 64).

## BYCATCHES

Harvesters are obliged to have an at-sea observer on board at the Department's request. The At-Sea Observer Program aims at 5\% coverage of all shrimper fishing trips. These observers record detailed information on tows (position, duration, and catch per species or taxon and, for some species, specimen length). Data from the At-Sea Observer Program that were used for this study were collected between 2000 and 2021 during the northern shrimp fishing in the Estuary and Gulf of St. Lawrence with the goal to estimate the bycatches.
The methodology for data processing of bycatches is presented in Savard et al. (2013). Since 2000, 24,197 tows were sampled. The positions of the observed tows from 2019 to 2021 are presented in Figure 65. Weighting factors ( $\sum$ shrimper effort/ $\sum$ observer effort) were calculated and used to scale the bycatch results to the total effort deployed by the fleet (Table 30 and Table 31).
From 2000 to 2012, average annual bycatches totalled about 500 t (Table 32 and Figure 66). Since 2013, these bycatches have increased rapidly, reaching a historical peak of over $1,500 \mathrm{t}$ in 2016 before beginning to decline again. Bycatches were 470 t and 449 t in 2020 and 2021 respectively, values comparable to those observed before 2012. The upward trend that began in 2013 can be explained by the increase in catches of small redfish as a result of the strong redfish recruitment observed in recent years (Senay et al. 2019). Redfish catches have nonetheless been declining since 2018 (Figure 69). The decrease in redfish bycatches is attributable to the fact that the fish are now larger and cannot fit through the openings in the Nordmore grate. In 2019, Greenland halibut catches rose to 203 t compared with an average level of less than 100 t (Figure 71). The majority of Greenland halibut catches were made in the Sept-lles area and this increase corresponded to a year of strong recruitment, i.e. the 2018 cohort (Gauthier et al. 2021). These catches decreased in 2020 and 2021 to less than 80 t, i.e. values below the historical average. Witch flounder (Glyptocephalus cynoglossus) catches have
been above average since 2016 (Figure 73) and can be explained by an increase in the abundance of this population in the nGLS (Bourdages et al. 2022).

The bycatch estimate is compared with shrimp catches to obtain a ratio of bycatches to the total shrimp catch (Table 32 and Figure 67). From 2000 to 2012, the ratios varied between $1 \%$ and $2 \%$. The ratio began to increase in 2013 and has remained at a level of over 4\% from 2016 to 2019. This upward trend is mainly due to a significant increase in catches of small redfish. In 2020 and 2021, the ratio has decreased and stands at $2.6 \%$.

In 2021, the main species in bycatches were, in order of importance, redfish, Greenland halibut, capelin, witch flounder, herring (Clupea harengus), American plaice (Hippoglossoides platessoides) and white barracudina (Arctozenus risso) (Table 33 and Table 34). These species are commonly caught in the shrimp fishery and are present in more than $70 \%$ of tows. Fish bycatches were mostly in the range of 1 kg or less per species per sampled tow.

Bycatches are compared to the biomass and population estimates derived from DFO's annual trawl survey in the Estuary and northern Gulf of St. Lawrence between 2000 and 2021 (Bourdages et al. 2022). The total estimated bycatch by species nonetheless represents less than $1 \%$ of their respective estimated biomass based on the DFO survey results (Table 35).

The geographical distributions of bycatches during fishing activities directed on shrimp in presence of an at-sea observer are presented for Atlantic cod, redfishes, Atlantic halibut, Greenland halibut, American plaice, witch flounder and capelin. The average of catches (kg/tow) of all tows in a same square of 5 minutes is made annually (2020 and 2021) (Figure 68 to Figure 74). Length frequencies are available for Atlantic cod, redfishes, Atlantic halibut, Greenland halibut, American plaice and witch flounder (Figure 68 to Figure 74).

Catches of other shrimp species during commercial fishing activities are very low compared to northern shrimp catches. Two shrimp species are common in catches: white shrimp (Pasiphaea multidentata) and Aesop shrimp (Pandalus montagui). From 2000 to 2021, the percentage in the total $P$. multidentata catch observed at sea was $0.08 \%$ (Table 33) and in landings, $0.78 \%$ (Table 36); for $P$. montagui, the percentages observed were $0.02 \%$ at sea and $0.17 \%$ in landings.

## RESEARCH

The different scientific research projects can be linked to various components of the integrated fisheries management plan (IFMP) for shrimp in the GSL. The issues identified in the consultations held in connection with IFMP development are as follows:

- Sustainable harvesting of shrimp;
- Impacts of fishing on the ecosystem;
- Governance of the fishery;
- Economic prosperity in the fishery.

The issues the fishery faces have helped define the objectives of the integrated management plan and the research projects were developed to provide possible solutions for these issues.

The scientific research projects carried out on northern shrimp by scientists with the Maurice Lamontagne Institute are funded in whole or in part under DFO's national programs and presented in Appendix 1. They are directly aligned with the priority directions set out in the scientific framework documents and are part of the strategic research program of the Ecosystem Science sector. These projects will be complemented by initiatives funded by the

DFO Core Program (research surveys, dockside and at-sea sampling, logbooks and vessel monitoring system) which are directly linked to monitoring of stock status, the ecosystem and the fishery.

## CONCLUSION

With warming and oxygen depletion in deep waters in recent years, a shift of northern shrimp to shallower depths has been observed. They are closer to the CIF to find colder and oxygenated waters. The northern shrimp therefore finds itself trap between the deep layer which is warming and the CIL. With this shift, there is a reduction in the realised habitat by the shrimp of more than $50 \%$ throughout the nGSL. By concentrating on smaller areas, it is therefore more vulnerable to predation and the impact of fishing. Fishermen have successes to maintain or improve CPUE in recent years when the population biomass is at its lowest historical level. Commercial fishery data does not reflect stock status and exploitation rates are increasing.

Changes observed in the ecosystem, the increase in the exploitation rate and uncertainty surrounding the stock status indicator indicate that there is an increased risk of undesirable biological and ecological consequences for the sustainability of the stocks and ecosystem (Table 37). Currently, the risk to stock sustainability is greater than it was during the reference period used in establishing the PA. Warming and oxygen depletion in deep waters, combined with heavy predation by redfish, are not expected to improve in the short to medium term.

The current ecosystem conditions differ from the conditions that existed when the precautionary approach was developed in the early 2010s. The uncertainties are greater. The sum of evidence indicates that we are currently working outside of the framework in which the PA was developed. In order to reduce the biological risks for these populations and the ecological risk, fishing pressure should be reduced. The harvests projected by the PA should be conditioned downwards considering the sensitivity of the shrimp and that we are at the extreme of the preferential conditions for this species.

## ACKNOWLEDGEMENTS

Sincere thanks to the numerous technicians who have collected and analysed the samples of the commercial fishery as well as to the shrimp fishermen who filled the log-books. As well as to the numerous biologists and technicians who have participate to the DFO ecosystemic survey. Finally to Jordan Ouellette-Plante and Stéphane Plourde for reviewing this document

## TABLES

Table 1. Importance of northern shrimp in the Greenland halibut and redfish diets, according on the period and length class considered. For each period / length class combination, the frequency of occurrence (Focc), the mass contribution (MC, in \%), the partial fullness index (PFI) and the contribution to the TFI (\% TFI) of the northern shrimp in the $N$ stomachs available are provided.
Greenland halibut

Table 9. Weighting factors used to estimate the numbers at length by fishing area (SFA), by year and by month. The catch corresponds to the landing that is adjusted for the proportion (ratio) of $P$. borealis in the samples. The origin (month, year) of the samples used for the estimated is also indicated.

+ : From 2008, the sampling was increased with the addition of strata in shallow waters ( 37 to 183 m ) in the
Estuary.

Table 24. Limit reference points (LRP) and upper stock reference point (USR) of Precautionary Approach for northern shrimp in the Estuary and Gulf of St. Lawrence.

| Stock | LRP | USR |
| :--- | :---: | :---: |
| Estuary (SFA 12) | 0.65 | 1.12 |
| Sept-Iles (SFA 10) | 0.53 | 1.33 |
| Anticosti (SFA 9) | 0.60 | 1.18 |
| Esquiman (SFA 8) | 0.45 | 1.34 |

Table 25. Standardized indices for the main indicator of stock status calculated from commercial fishery indices (NUE) and from the DFO (Abd) by fishing area.

Table 26. Guidelines defining removal rates ( $P$ ) based on the main stock status indicator (I) of Precautionary Approach for northern shrimp in the Estuary and Gulf of St. Lawrence.

| Stock | Critical zone | Cautious zone | Healthy zone |
| :--- | :---: | :---: | :---: |
| Estuary (SFA 12) | $P=117.7 I$ | $P=-551.8+962.4 I$ | $P=470,7 I$ |
| Sept-Iles (SFA 10) | $P=1469.7 I$ | $P=-3910.5+8819.4 I$ | $P=5868.9 /$ |
| Anticosti (SFA 9) | $P=1044.1 I$ | $P=-419.6+7819.1 I$ | $P=4176.4 I$ |
| Esquiman (SFA 8) | $P=881.0 I$ | $P=-1808.8+4871.1 I$ | $P=3524.0 I$ |

Table 27. Projected harvest for 2020 by the main stock status indicator.

| Fishing area | SFA | Main indicator | Classification <br> zone | Projected <br> harvest (t) |
| :--- | :---: | :---: | :---: | :---: |
| Estuary | 12 | 1.185 | Saine | 558 |
| Sept-lles | 10 | 1.151 | Prudence | 6242 |
| Anticosti | 9 | 1.299 | Saine | 5425 |
| Esquiman | 8 | 1.441 | Saine | 5079 |

Table 28. Environmental conditioning factors (ECFs) for GSL northern shrimp stocks with projected harvests conditioned for a changing environment or following the current precautionary approach (status quo).

| Fishing <br> area | ECF (1-ECF) | Harvests 2022 (t) <br> conditioned for a changing <br> environment | Projected harvests 2022 (t) <br> (status quo) |
| :--- | :---: | :---: | :---: |
| Estuary | $0.85(0.15)$ | 474 | 558 |
| Sept-Iles | $0.85(0.15)$ | 5306 | 6242 |
| Anticosti | $0.83(0.17)$ | 4513 | 5425 |
| Esquiman | $0.83(0.17)$ | 4224 | 5079 |

Table 29. Spatial distribution of fishing effort in hours and trawl surface according to VMS data according to the trawl footprint of the northern shrimp fishery. An intensity of $50 \%$ means that the area of a square of 1 degree longitude-latitude has been trawled at $50 \%$ in a year.

Fishing effort (hour)

| Year | Footprint |  |  |  |  |  |
| :---: | ---: | ---: | ---: | ---: | ---: | ---: |
|  | Low |  | Medium |  | High |  |
|  | $>0 \%$ | $>10 \%$ | $>25 \%$ | $>50 \%$ | $>100 \%$ | $>200 \%$ |

## APPENDICES

## Appendix 1. DFO Strategic Research Plan for Northern Shrimp in the Estuary and Gulf of St. Lawrence.

The various scientific research projects can be associated with various components of the integrated management plan for the shrimp fishery in the Estuary and Gulf of St. Lawrence. The issues identified at the end of the consultations to develop the IFMP are as follows:

- sustainable harvest of shrimp;
- the impacts of the fishery on the ecosystem;
- fishery governance;
- the economic prosperity of the fishery.

The issues facing the fishery have allowed us to define the objectives of the integrated management plan and the research projects have been developed to provide potential solutions to these issues.

Scientific projects conducted on the northern shrimp by scientists from the Maurice Lamontagne Institute (MLI) are funded in whole or in part by DFO national programs. They respond directly to priority directions presented in the scientific frameworks and are part of the Ecosystem Science strategic research program. These projects are completed by initiatives funded by the DFO's core program (research surveys, dockside and at-sea sampling, logbook and Vessel Monitoring System) directly related to monitoring the status of stocks, the ecosystem and the fishery.

## Theme A. Shrimp productivity and their sustainable harvesting

To effectively manage the fisheries, an in-depth understanding of the productivity of the population being harvested is required. Changes in the productivity and resiliency of key species can have serious consequences on the overall dynamics of all ecosystems and on the sustainability of fisheries. These changes may be triggered by a number of biological, physical and environmental factors as well as by human activities.

## Sub-topic A1. The abundance of shrimp stocks in the Estuary and Gulf

- Status assessment of shrimp stocks by ongoing monitoring activities intended to calculate stock status indicators and determine the appropriate fishery catch shares consistent with the precautionary approach.
DFO core program
Hugo Bourdages and collaborators

## Sub-topic A2. The trophic relationships between the shrimp and its predators

- Study of the diets of the main groundfish.

DFO core program
Denis Chabot and collaborators

- Winter survey in the Laurentian channel and the northern gulf of St. Lawrence.

DFO (C-68)
Hugo Bourdages and Jenni McDermid

## Sub-topic A3. Environmental factors influencing the shrimp's productivity

- Status assessment of the physical and biochemical oceanographic environment of the Gulf of St. Lawrence by continuing the Atlantic Zone Monitoring Program to detect, monitor and predict changes in productivity and marine environment status.
DFO core program
Peter Galbraith and collaborators
- Assessment of synergic effects of various environmental stressors combined with acidification on the physiology, the growth or the survival of invertebrates that are harvested commercially in the St. Lawrence.
Strategic Program for Ecosystem-Based Research and Advice, DFO, 2014-2023 Denis Chabot and collaborators
- Linking physiology to biogeography of Northern shrimp to facilitate adaptation to climate change.
Strategic Program for Ecosystem-Based Research and Advice, DFO, 2017-2023 Denis Chabot, Piero Calosi (UQAR) and collaborators
- PANOMICS: Integrating genomics to current and future spatial management of northern shrimp (Pandalus borealis) along the Canadian coast.
Genomics Research and Development Initiative, DFO, 2019-2022
Geneviève Parent and collaborators
- Groundfish return in the Estuary and Gulf of St. Lawrence.

Partnership Fund, 2017-2020
DFO : Hugo Bourdages, Hughes Benoît, Denis Chabot, Daniel Duplisea, Marie-Julie Roux and collaborators
Ressources Aquatiques Québec : Céline Audet, Dominique Robert, Steve Plante, Pascal Sirois, Louis Bernatchez and collaborators

- REDTANKS : Understand the environmental needs and the consumption of shrimp by redfish (Sebastes spp.) with experiments in tanks.
Results funds, DFO, 2019-2022
Denis Chabot, Caroline Senay, Geneviève Parent and collaborators
- Development of a qualitative network modeling tool

Ecosystemic approach, DFO, 2019-2021
Marie-Julie Roux and Daniel Duplisea

- Development of risk conditioning factors associated to fishing removals in a context of climate change.
DFO, 2019-2022
Marie-Julie Roux and Daniel Duplisea

## Theme B. The fishery's impact on the ecosystem

Fisheries Management's decisions must take into consideration targeted and non-targeted species, the ecosystems of which they are a part and the impact of fishing on these ecosystems. This is the basis of an ecosystem-based approach to fisheries management, which, along with a precautionary approach, constitutes the key to the new sustainable development framework of Fisheries and Oceans Canada. In compliance with the United Nations Food and Agriculture Organization's (FAO) Code of Conduct for Responsible Fisheries, DFO promotes responsible fishing aimed at reducing bycatch and mitigating impacts on habitat wherever biologically justifiable and cost effective.

## Sub-topic B1. Vulnerable benthic habitats and communities

- Study of the distribution, spatial structure, reproduction, ecosystem function and vulnerability to trawling of sea pen fields in the Gulf of St. Lawrence in support of the "Eastern Canadian Coral and Sponge Conservation Strategy".
Strategic Program for Ecosystem-Based Research and Advice, DFO, 2014-2017
Bernard Sainte-Marie, Hugo Bourdages, Catherine Couillard, Claude Savenkoff
Sub-topic B2. Species not targeted by the fishery
- Assessment of the significance of shrimpers' bycatch by analyzing data from the At-Sea Observer Program activity monitoring.
DFO core program
Hugo Bourdages and collaborators
