Foreword

This series documents the scientific basis for the evaluation of aquatic resources and ecosystems in Canada. As such, it addresses the issues of the day in the time frames required and the documents it contains are not intended as definitive statements on the subjects addressed but rather as progress reports on ongoing investigations.

ABSTRACT

In the Estuary and Gulf of St. Lawrence, four assessment units have been used since 1993 for the assessment of northern shrimp stocks, namely the Estuary, Sept-Iles, Anticosti and Esquiman areas. These stock assessment units correspond to locations where high concentrations of shrimp are generally observed during the research survey.

Information on northern shrimp abundance and the distribution of fishing effort over the last several decades suggests that the stock assessment units in the Estuary and northern Gulf of St. Lawrence need to be changed. A new delineation of the stock assessment units is proposed and supported by findings from a population genomics study. The stock indicators have been updated based on the new delineation, which provides an improved correspondence between assessment units and biological units.

INTRODUCTION

In 1993, the management units for the northern shrimp stocks in the Estuary and northern Gulf of St. Lawrence (ENGSL) were redefined to take into account the distribution of shrimp and contemporary fishing patterns (Figure 1). As part of this process, the number of management units was reduced from five to four, specifically the Estuary, Sept-Iles, Anticosti and Esquiman (Figure 2) (shrimp fishing areas (SFA) 12, 10, 9 and 8, respectively). These four units were redefined so that they would better correspond to the biological units based on the knowledge available at the time. Since the ENGSL is a highly dynamic environment, it is possible that the biological boundaries of these stocks may have changed since the last time they were delineated. A number of factors could cause changes in the species' distribution and abundance, including climate-driven changes and pressure from competing or predatory species. Besides, new knowledge can be used to better define the existing biological units.

Several of the terms used in this document need to be defined from the outset, since the definitions used in the literature may differ among studies depending on the topic being addressed (e.g. stock assessment, genomics). A stock may be described as a semi-distinct group of individuals of a given species that have some definable attributes in common which are of interest to fisheries managers and that can be assessed as a unit (DFO 2023). Alternatively, a stock may be defined on a functional basis for the purpose of fisheries management, in part due to uncertainties in defining spatial and temporal boundaries for biological units or due to historical considerations related to the fisheries. It is generally recognized that stocks should be defined on the basis of biological information first, after which management needs can be considered (Cadrin 2020). In this document, a stock refers to the individuals in an assessment or management unit. A biological unit can be defined as a group of individuals that have some attributes and characteristics in common, including the fact that they occupy the same space and have limited contact with other, similar groups. A biological unit may be more accurately defined as a population if it consists of a group of individuals that seldom breed with, or are reproductively isolated, from other groups (Waples and Gaggiotti 2006). Population genomic analyses enable information to be collected on the reproductive isolation between populations, among other things.

It is easier to assign a limit reference point (LRP, the level below which serious harm could occur to the resource) to a stock when the defined management unit is the same as the biological unit (Cadrin 2020). This match between the spatial and temporal scales at which biological processes and management and assessment activities occur helps to ensure the efficacy of stock assessment and management systems aiming to avoid serious harm to stocks. Therefore, the indicators, LRPs and stock status metrics should be selected based on the best available information for the stock.

During the stock assessment conducted in winter 2022 (DFO 2022), it was concluded that the precautionary approach should be revised before the next assessment. This revision was considered justified because ecosystem conditions were no longer the same as when the precautionary approach was developed in the early 2010s (DFO 2011) and because bias had been observed in the main stock status indicator. Furthermore, northern shrimp stocks are now prescribed stocks pursuant to section 6 in the modernized *Fisheries Act*, Bill C-68, which came into force on April 4, 2022. A new LRP must be established for all prescribed stocks in keeping with the guidelines associated with the fish stocks provisions (DFO 2023).

The need to adjust the LRP for the different shrimp stocks in the ENGSL provided the opportunity to review the assessment units for shrimp stocks in light of new information on the species' spatial distribution, the distribution of fishing effort and the genomic structure of the

stocks, in order to ensure that the stock status indicators provide a reliable picture of the biological units.

The geographic locations mentioned in the text and the bathymetry of the Estuary and the Gulf of St. Lawrence are presented in Figure 3.

DELINEATION OF BIOLOGICAL UNITS

In the ENGSL, the sites with the greatest shrimp abundance are separated by a considerable distance. All maturity stages (juveniles, males and females) are present at these sites (Bourdages et al. 2022b), which indicates that the capacity to ensure a certain level of recruitment to the population exists.

HISTORY OF MANAGEMENT UNITS

In the early 1980s, five management units were established for the shrimp fishery based on the five areas exploited by harvesters, specifically the Estuary, Sept-Iles, North Anticosti, South Anticosti and Esquiman areas (Figure 2). Already in 1978, stock assessments were based on this delineation (CAFSAC 1978). However, the expansion of the fishery during the 1980s raised questions about some of the boundaries between these management units. During the stock assessment in 1992 (CSCPCA 1992) and at the second symposium on Gulf of St. Lawrence shrimp, held in 1993 (Savard and Boudreau 1993), it was recommended that the management units be restructured to better reflect fishing activities and prevent conflicts.

Accordingly, the management units were modified in 1993 so that their boundaries would better reflect fishing patterns, which are determined by the spatial distribution of areas with high concentrations of shrimp. At the time, there were four spatially isolated areas with substantial concentrations of shrimp, namely the Estuary, Sept-Iles, Anticosti and Esquiman areas (Figure 2). The boundaries between the management units adopted in 1993 were located in sectors where no fishing was carried out and shrimp abundance was low.

POPULATION GENOMICS

A population genomics study was conducted on 1,513 adults of northern shrimp, predominantly females, from 54 stations sampled between May and December 2019 in the area from Davis Strait to the Bay of Fundy. The sampling included 231 individuals from 8 stations in the ENGSL (Figure 4A). This study allowed knowledge acquisition on the species' connectivity and its vulnerability to climate change (Bourret et al. in prep.¹). The shrimp were genotyped using 14,331 genomic markers consisting of single nucleotide polymorphisms (SNPs). The markers were obtained through a genotyping-by-sequencing approach, namely ddRADseq (Poland et al. 2012).

Results from this study using the full set of genomic markers suggest that the shrimp in the ENGSL form a distinct population from the populations of the Scotian Shelf and Newfoundland/Labrador/Arctic. The levels of genetic differentiation (F_{st}) between the ENGSL ($n = 231$) and these adjacent populations range from 0.0006 (Newfoundland/Labrador/Arctic, $n =$

¹ Bourret, A., Leung, C., Puncher, G., Le Corre, N., Deslauriers, D., Skanes, K., Bourdages, H., Di Cassista Ross, M., Walkusz, W., Jeffery, N. W., Stanley, R. E. E., Parent, G. J. 2023. Diving into large scale genomics to decipher drivers of structure and climatic vulnerability in a widespread marine shrimp. In preparation.

823) to 0.0018 (Scotian Shelf, $n = 345$; $P < 0.001$). These results point to a reduced level of connectivity between the three populations.

Furthermore, based on the genomic marker data, the connectivity between some management units in the ENGSL appears to be limited. The shrimp from two stations (i.e., 8-1 and 8-2) in the Esquiman management unit show levels of genomic differentiation that are significantly different from most stations in the ENGSL (average $F_{st} = 0.0006$, Figure 4B). The average F_{st} estimated for shrimp at stations 8-1 and 8-2 appears to be equivalent to that between the ENGSL and Newfoundland/Labrador/Arctic populations. However, the sample size for stations 8-1 and 8-2 is smaller, and the error associated with this estimated F_{st} is greater. By contrast, Savard et al. (1993) did not observe a genetic difference in their study which involved the use of eight enzyme-based genetic markers. The genomics study of Bourret et al. (in prep.²), which used a much larger number of genetic markers, enabled the detection of lower levels of genetic differentiation between management units. These levels of genetic differentiation, albeit low, are significant and therefore provide information that can be used to identify reproductive isolation between the groups of shrimp in the ENGSL.

At the scale of the genomics study (Davis Strait to Bay of Fundy), the explanatory analyses of genomic variance show that the genomic structure of northern shrimp is strongly linked to environmental gradients such as temperature and salinity in the surface or bottom layer (Bourret et al. in prep.²). At this scale, 249 loci on the 14,331 genomic markers were identified as possibly being linked to adaptations to the environment. In the ENGSL, the adaptive landscape constructed with these adaptive loci is not spatially homogeneous and suggests local adaptation or selection driven by environmental conditions. These results suggest that the selective pressures projected for the year 2075 in the ENGSL would have a greater effect on shrimp in the Estuary and western Gulf of St. Lawrence (i.e., the Estuary, Sept-Iles and Anticosti management units) and a lesser effect on shrimp in the eastern Gulf of St. Lawrence (i.e., the Esquiman management unit).

The proposed changes to the boundaries of the stock assessment units in the ENGSL appear to slightly improve genetic homogeneity between the units using the 249 adaptive loci. The four present management units explain a significant proportion of the genetic variance observed at the adaptive loci in northern shrimp (Table 1), which provides support for the use of these units. The proposed modification to the stock assessment units (i.e., incorporate 9-2 in unit 10, Figure 4A) explains a larger proportion of the genomic variance (0.80%) than that explained by the current units (0.51%; with a slightly lower AICc for the new units). The increase in the amount of variance (difference of 0.29%) explained is substantial in a context of genomic analysis. A delineation separating unit 8 from units 9, 10 and 12 to reflect the limited connectivity between Esquiman and the western part of the ENGSL would explain a slightly smaller proportion of the genetic variance than the proposed changes (0.78%). It should be noted that the amount of genetic variance explained by the current management units and the proposed ones is not significant when the entire set of genetic markers is used (i.e., 14,311 markers).

DISTRIBUTION OF FISHING EFFORT

The sectors that sustain the fishery in the four management units correspond to locations where large concentrations of shrimp are generally observed during the research survey (see below).

² Bourret, A., Leung, C., Puncher, G., Le Corre, N., Deslauriers, D., Skanes, K., Bourdages, H., Di Cassista Ross, M., Walkusz, W., Jeffery, N. W., Stanley, R. E. E., Parent, G. J. 2023. Diving into large scale genomics to decipher drivers of structure and climatic vulnerability in a widespread marine shrimp. In preparation.

Fishing intensity therefore varies in both space and time as a function of stock abundance (Figure 5).

In the Estuary, fishing is concentrated on the north slope of the Laurentian Channel between Portneuf-sur-Mer, to the west, and Pointe des Monts, to the east. Beginning in 2011, a shift in fishing effort from east of the Manicouagan Peninsula to west of this peninsula was observed. Since 2014, more than 96% of the catch has come from shallower depths in the area west of this peninsula.

Fishing was conducted on the north slope of the Gaspé Peninsula and from there eastward to the south slope of the Laurentian Channel from 1994 to 2017. Since then, very little or no fishing effort has taken place on the south slope of the Laurentian Channel.

In the western Gulf, fishing activities are distributed between Pointe des Monts and the area south of Parent Bank to the west of Anticosti Island. The distribution of fishing effort is shaped like a crescent that follows the seafloor bathymetry along the North Shore. Harvesters have abandoned the sector south of Parent Bank in recent years.

After the management units were modified in 1993, the distribution of shrimp showed an eastward expansion to an area south of Anticosti Island beyond the boundary separating the Sept-Iles and Anticosti management units (Figure 5). As early as 1994, fishing began to take place in the Anticosti management unit, specifically in the sector south of Anticosti Island (Figure 6). From 1995 to 2006, approximately 50% of the TAC was taken in the sector south of the island (in the Anticosti management area), whereas little or no fishing was carried out in this sector prior to 1992. The boundary south of Anticosti Island therefore no longer corresponds to the delineation rationale applied in 1993 for these units, which involved locating boundaries in sectors of low shrimp abundance in order to separate them from zones with large shrimp concentrations exploited by the industry. From 1993 to 2007, a significant amount of fishing took place in the area south of the island in the Anticosti unit. However, in subsequent years, the entire TAC, or most of it, was taken north of the island.

In the area north of Anticosti Island, fishing is distributed in the Anticosti Channel from Jacques-Cartier Strait to Beaugé Bank.

In the eastern Gulf, on the west coast of Newfoundland (NAFO Division 4R), fishing is concentrated in the Esquiman Channel, that is, from the head of the channel, which is bordered to the north by the Strait of Belle Isle, southwestward in the depths of the channel right to Beaugé Bank. No fishing effort has occurred south of the 49th parallel in Division 4R.

The distribution of shrimpers' fishing effort in the ENGSL has varied over time as a function of shrimp abundance and distribution. When there is an increase in shrimp abundance, the distribution of fishing effort expands as well. In contrast, when abundance decreases, fishing effort becomes more concentrated. The main sectors sustaining the fishery in the four management units have changed little over the years and correspond to the locations where the highest concentrations of shrimp have been observed during the research survey. However, in recent years, harvesters have abandoned some fishing grounds because of the low shrimp abundance. This includes the area east of the Manicouagan Peninsula in the Estuary, the northeastern tip of the Gaspé Peninsula, the area southeast of Anticosti Island, and the southwestern part of the Esquiman Channel (Figure 7).

DISTRIBUTION OF NORTHERN SHRIMP

Every summer since 1990, DFO has conducted a research trawl survey in the ENGSL with the goal of assessing the abundance of several species, including shrimp (Bourdages et al. 2022a). This survey is the main source of fishery-independent data for the assessment of northern

shrimp stocks in the ENGSL. It provides information that is used to describe the distribution of northern shrimp, estimate the abundance and biomass of the stocks, and determine stock dynamics, among other things. The survey covers an area of 118,391 km² and extends to depths of over 37 m. Northern shrimp is generally confined to depths greater than 150 m, beneath the cold intermediate layer (CIL). The survey is therefore considered to provide good coverage of the distribution of northern shrimp in the ENGSL.

Following the decline in the abundance of large groundfish species in the early 1990s, shrimp abundance and biomass followed an increasing trend until the 2010s. Beginning in 1990, an increase was observed in the area occupied by shrimp, which went from 65,000 km² to over 90,000 km² in 1994 (Figure 8), with the same trend observed for their area of concentration. This increasing trend in the distribution area of shrimp was observed in all four stocks. Since 2008, however, there has been a decrease in the area where shrimp concentrate, that is, the minimum area where over 95% of the biomass is distributed. This area has decreased from over 50,000 km² to less than 30,000 km². Northern shrimp are now mainly concentrated at the heads of channels (Figure 9).

In the northern GSL, there are several locations where the abundance of shrimp is low. The low levels of abundance can be explained by the unsuitability of the habitat due to the water depth. The surface layer, depths that intersect the CIL, and depths greater than 350 m are not suitable habitat for the species. The main areas of spatial discontinuity in the GSL are the Jacques Cartier Strait, the Strait of Belle Isle, Beaugé and Parent Banks, and the deep Laurentian Channel.

Additionally, shrimp size has been found to vary along an east-west gradient, with the smallest individuals observed in the Esquiman Channel and the largest in the Estuary.

The distribution of northern shrimp in the ENGSL has thus been influenced by the size of the shrimp stocks. Whether shrimp abundance is low or high, the concentration areas where the highest abundances of shrimp in a given stock are observed, specifically at the heads of channels, have not changed. Furthermore, regardless of the time period, there are spatial discontinuities between these areas of large shrimp concentrations which are delineated by sectors with low abundances.

DEFINITION OF PROPOSED ASSESSMENT UNITS

Although northern shrimp are widely distributed in the ENGSL and fishing has been carried out in a variety of sectors over the years, the major shrimp concentrations are confined to a few fairly well-defined areas. The proposed assessment units are defined below taking into account areas of discontinuity in the distribution of shrimp as well as population genomics findings (Figure 2).

Estuary

The Estuary assessment unit is defined as being located west of Pointe des Monts at longitude 63°27'W. Even if shrimp are distributed both to the north and south of the Laurentian Channel, the main concentrations are found north of the channel.

With the increase in water temperatures and the depletion of oxygen in the bottom layer, a significant shift of shrimp to new depths was observed in the Estuary beginning in 2018 (Bourdages et al. 2022b). For example, between 2008 and 2017 females were found at depths of between 110 and 320 m; however, since 2018, they have been found closer to the CIL, at depths of between 70 et 170 m. This depth-based change in distribution is very pronounced in the Estuary but is present to a lesser extent in the other units where the waters are continuing to

warm and become more depleted in oxygen. In addition, redfish abundance is lower in the Estuary unit than in the other assessment units (Senay et al. 2023). In light of these observations, it is considered appropriate to maintain the present boundary between the Estuary and Sept-Iles assessment units.

The Estuary assessment unit has nonetheless been expanded so that it corresponds to the area covered by the DFO survey which was expanded in 2008 to incorporate the 37 m to 183 m depth strata (Figure 10, strata 851, 852, 854 and 855). This new definition of the assessment unit represents an improved correspondence with the biological unit and takes into account the changes in shrimp distribution.

Sept-Iles

The Sept-Iles assessment unit is bounded on the west by the longitude of Pointe des Monts and on the east along the North Shore by the Strait of Jacques Cartier, which is located northwest of Anticosti Island (shallow area). The area also includes the portion of the Laurentian Channel south of Anticosti Island to the boundary linking the eastern tip of Anticosti Island and the junction of NAFO Divisions 4RST in the middle of the Laurentian Channel, an area of discontinuity in the distribution of shrimp. This area is also characterized by the counter-clockwise currents of the Anticosti Gyre (Figure 11). The change to the southeastern boundary of this area increases the genomic consistency (i.e. a greater amount of adaptive genomic variance is explained) of this proposed stock assessment unit.

Anticosti

The Anticosti assessment unit corresponds to the Anticosti Channel, which is located north of Anticosti Island. Shrimp aggregations are found mainly within the channel, particularly at its head. This unit is separated from the Sept-Iles unit by the shoals of the Jacques Cartier Strait, which is located farther to the west, and by Anticosti Island to the south. It is also separated from the Esquiman unit to the east by Beaugé Bank (a shallower zone) and by the deep Laurentian Channel. In addition, the change to the southwestern boundary of this unit enhances the genomic consistency (i.e., a greater amount of adaptive genomic variance is explained) of this proposed stock assessment unit.

Esquiman

The Esquiman assessment unit corresponds to NAFO Division 4R and the northeastern part of Division 4S east of the 60th parallel. Shrimp aggregations occur mainly at the head of the Esquiman Channel. There is a spatial discontinuity in the distribution of shrimp between the Esquiman and Anticosti units which is attributable to the topography. Beaugé Bank (a shallower zone) serves as a natural boundary between these two units as does the deep Laurentian Channel to the south of Division 4R. The shrimp present in the Esquiman Channel appear to be genomically differentiated from, and have a different adaptive potential than, the shrimp in the other assessment units in the ENGSL (Figure 4).

In summary

In light of these new definitions of the biological units, it is proposed that the assessment units be modified to provide a better spatial alignment of the stock status indicators with the biological units. In summary, the proposed modifications are:

- The stock assessment unit for the Estuary is expanded to take into account research survey information from the trawl stations covering the 37 m to 183 m depth strata. The time series

of biomass indices begins in 2008, and the survey area corresponds to depths of over 37 m in the Estuary.

- The boundary separating the Sept-Iles and Anticosti management units is moved from the south-central part of Anticosti Island to the eastern tip of the island. The stock assessment unit Sept-Iles is enlarged eastward in the Laurentian Channel, and the unit Anticosti is reduced so that it corresponds mainly to the Anticosti Channel, that is, the area north of the island.

UPDATE OF STOCK STATUS INDICATORS

The stock status indicators were recalculated based on the geographic boundaries of the proposed new stock assessment units. The use of georeferenced data makes it possible to obtain updated indicators representative of the proposed units, beginning in 1982 for landings and in 1990 for the biomass indices derived from the research survey.

In the case of landings, only those in the Sept-Iles and Anticosti stock assessment units were affected by the proposed changes in the units. The landings figures for the Estuary and Esquiman units remained unchanged as a result of the new unit delineations. Similarly, the biomass indices for the Sept-Iles and Anticosti assessment units also changed. In addition, the biomass indices for the Estuary unit changed from 2008 onwards, reflecting the fact that the sampling area was expanded to cover the 37 m to 183 m depth strata to correspond more closely to the current distribution of shrimp in this unit. The biomass indices for the Esquiman unit remain the same.

LANDINGS

Harvesters are required to describe their fishing activities in a logbook. The positions of fishing sites recorded by the harvester are used to identify the shrimp fishing area where fishing operations took place. Positions are expressed in latitude and longitude or by identifying the corresponding fishing quadrant (10 minutes of longitude by 10 minutes of latitude square, Figure 12), depending on the type of form provided to the harvester's fleet and the year. Since 1982, almost all catches have been georeferenced to at least the fishing quadrant level.

The logbook data obtained from the ZIFF (Zonal Interchange File Format) files correspond to one fishing day at a given site, with the resolution the same as that recorded in the logbook. Each catch in the ZIFF file was assigned to a proposed assessment unit based on the fishing quadrant where it took place.

The total catches recorded in the ZIFF files and the official DFO statistics on landings by shrimp fishing area, which can be found in the [Gulf Quota Reports](#), differ slightly. Consequently, the official DFO statistics were used as a baseline, and the ZIFF-file catches had to be adjusted proportionally so that, when totalled, they were equal to the official statistics. In addition, a second correction had to be made to the catch data, since some were not georeferenced to the fishing quadrant level (roughly 17% before 1990 and less than 1% from 1990 onwards, but only 5% and 0% in the Sept-Iles and Anticosti assessment units, respectively). Georeferenced catches were therefore adjusted proportionally so that their sum was equal to the official statistics. Following these corrections, the total catches in each quadrant were calculated annually for the current management units and the proposed stock assessment units. The resulting figures for landings per unit and year are shown in Table 2.

The modifications of the stock assessment units boundaries only affect the Sept-Iles and Anticosti units in the case of landings (Figure 13), and landings in the Estuary and Esquiman units did not change as a result of the new delineation of units. Since the Sept-Iles unit was

expanded to include a portion southeast of Anticosti Island, landings in that unit increased, while those in the Anticosti unit decreased. These changes in landings mainly affect the period from 1994 to 2006, since very few catches occurred in the portion southeast of Anticosti Island before and after this period.

Increases in landings in the Sept-Iles unit ranged from 11% to 61% (average 34%) during the 1994–2006 period, but averaged less than 1% during the period before 1994 and after 2006. Conversely, landings in the Anticosti area declined by 15% to 78%, or an average of 47%, during the 1994–2006 period, but only by approximately 1% during the period before 1994 and after 2006.

DFO SURVEY BIOMASS INDICES

Total biomass and the variance of estimates were kriged by using an interpolation grid covering the study area of the DFO survey. The method is presented in Bourdages et al. 2022b. Annual estimates were calculated for each assessment unit, based on the currently defined management units and the proposed assessment units. The results are shown in Tables 3 and 4 and Figure 15.

Beginning in 2008, the area covered in the DFO research survey in Division 4T was expanded to include the upstream portion of the Lower Estuary, in order to sample depths between 37 m and 183 m. Before 2008, only depths greater than 183 m were covered in the Estuary unit and consequently a portion of the stock was not sampled in the survey. The proposed Estuary assessment unit corresponds to the area sampled in the survey since 2008, and therefore is more representative of the biomass in this unit. Consequently, from now on, the time series will begin in 2008. The addition of these new, shallower depth strata has increased annual biomass by 684% on average, with annual increases ranging between 56% and 2,481%. The variations have been greater in recent years because of the movement of shrimp to shallower depths in order to reach the colder waters found there (Bourdages et al. 2022b).

The proposed expansion of the Sept-Iles assessment unit is associated with higher biomass estimates. For the 1994–2013 period, biomass increases in a range between 8% and 44%, with an average increase of 17%. However, for the years 1990–1993 and 2014–2022, the biomass are comparable, with annual increases of less than 10%. Since the area added to the proposed Sept-Iles assessment unit was taken from the Anticosti management unit, the opposite trend is observed in the latter, i.e. biomass values in the proposed Anticosti unit are smaller, with decreases ranging from 13% to 30% during the 1994–2013 period, with an average of 21%.

Since no modifications were made to the Esquiman assessment unit, biomass estimates there remain the same.

CONCLUSION

The sites in the ENGSL with the greatest shrimp abundance are spatially isolated from one another. In light of historical information on the distribution of fishing effort and shrimp in the ENGSL, as well as a recent population genomics study, it is proposed that changes be made to the stock assessment units in order to obtain a better spatial alignment between the stock status indicators and the biological units. In brief, these modifications involve expanding the Estuary assessment unit and moving the boundary between the Sept-Iles and Anticosti assessment units to south of Anticosti Island.

We were able to recalculate landings and biomass indices based on these new stock assessment units because this information was georeferenced. Therefore, indicators were defined based on the best information available on these stocks. The improved correspondence

between the assessment units and biological units will make it easier to assign a LRP to each stock.

The upcoming science advice and science advisory reports will be formulated based on the newly delineated stock assessment units presented in this document. Subsequently, Fisheries Management will decide on the spatial delineation of the stock management units in consultation with the industry.

TABLES

Table 1. Partitioning of genetic variance, taking into account the (A) current and (B) proposed assessment units or (C) by considering SFA 8 versus the other units (SFAs 9, 10, and 12). The analysis of genetic variance (AMOVA) was conducted using 249 adaptive loci. A corrected Akaike information criterion (AICc) was calculated for each model.

| Model | d.f. | SS | Variance | % of variance explained | P |
|---|------|--------|----------|-------------------------|-------|
| A) Current assessment units (AICc = 327.656) | | | | | |
| Between units | 3 | 15.71 | 0.02 | 0.51 | 0.043 |
| Within units (error) | 227 | 929.28 | 4.09 | 99.49 | - |
| Total | 230 | 944.99 | 4.11 | - | - |
| B) Proposed assessment units (AICc = 327.235) | | | | | |
| Between units | 3 | 17.40 | 0.03 | 0.80 | 0.013 |
| Within units (error) | 227 | 927.59 | 4.09 | 99.20 | - |
| Total | 230 | 944.99 | 4.12 | - | - |
| C) SFA 8 unit vs. other units (AICc = 329.632) | | | | | |
| Between units | 1 | 7.73 | 0.03 | 0.78 | 0.002 |
| Within units (error) | 229 | 937.26 | 4.09 | 99.22 | - |
| Total | 230 | 944.99 | 4.13 | - | - |

Table 2. Landings (t) by shrimp management unit, according to their 1993 definition (cur.) and the proposed (prop.) new stock assessment units. Years with a difference of more than 1% are shown in bold.

FIGURES

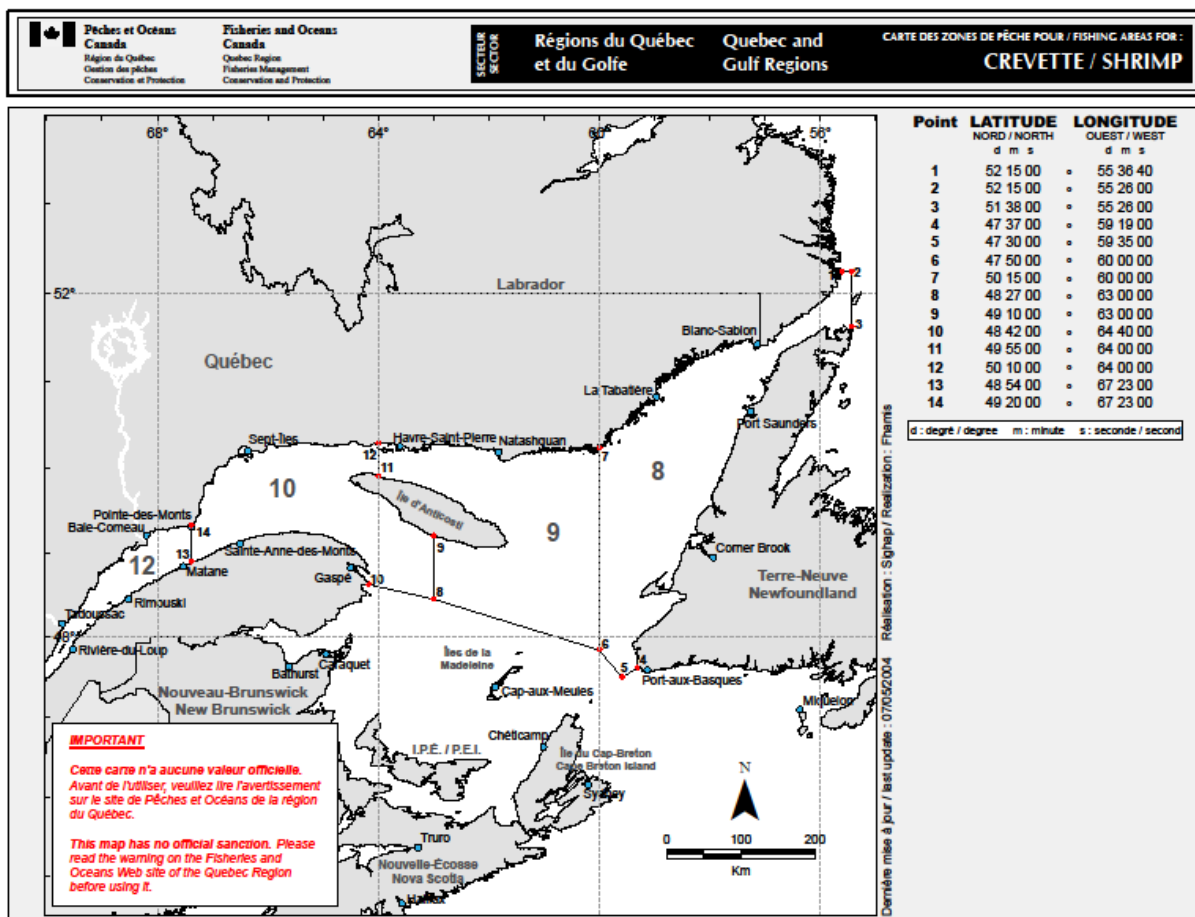

Figure 1. Management units (shrimp fishing areas) in the Estuary and Gulf of St. Lawrence as defined since 1993: Estuary (SFA 12), Sept-Iles (SFA 10), Anticosti (SFA 9) and Esquiman (SFA 8).

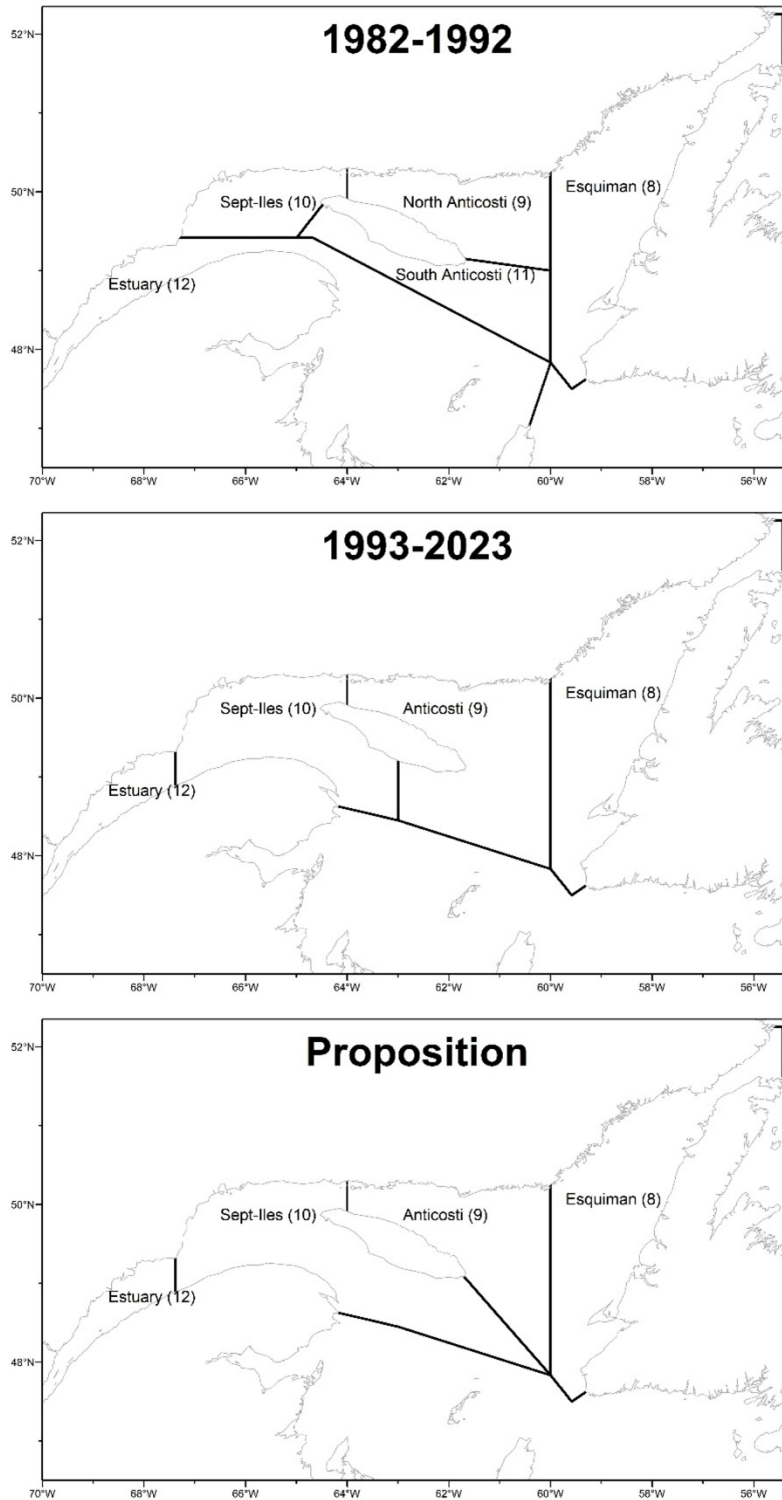

Figure 2. Shrimp fishing areas in the Estuary and Gulf of St. Lawrence as defined during the 1982–1992 and 1993–2023 periods and according to the proposed new delineations.

Figure 3. Bathymetry of the Estuary and Gulf of St. Lawrence and the locations mentioned in the text.

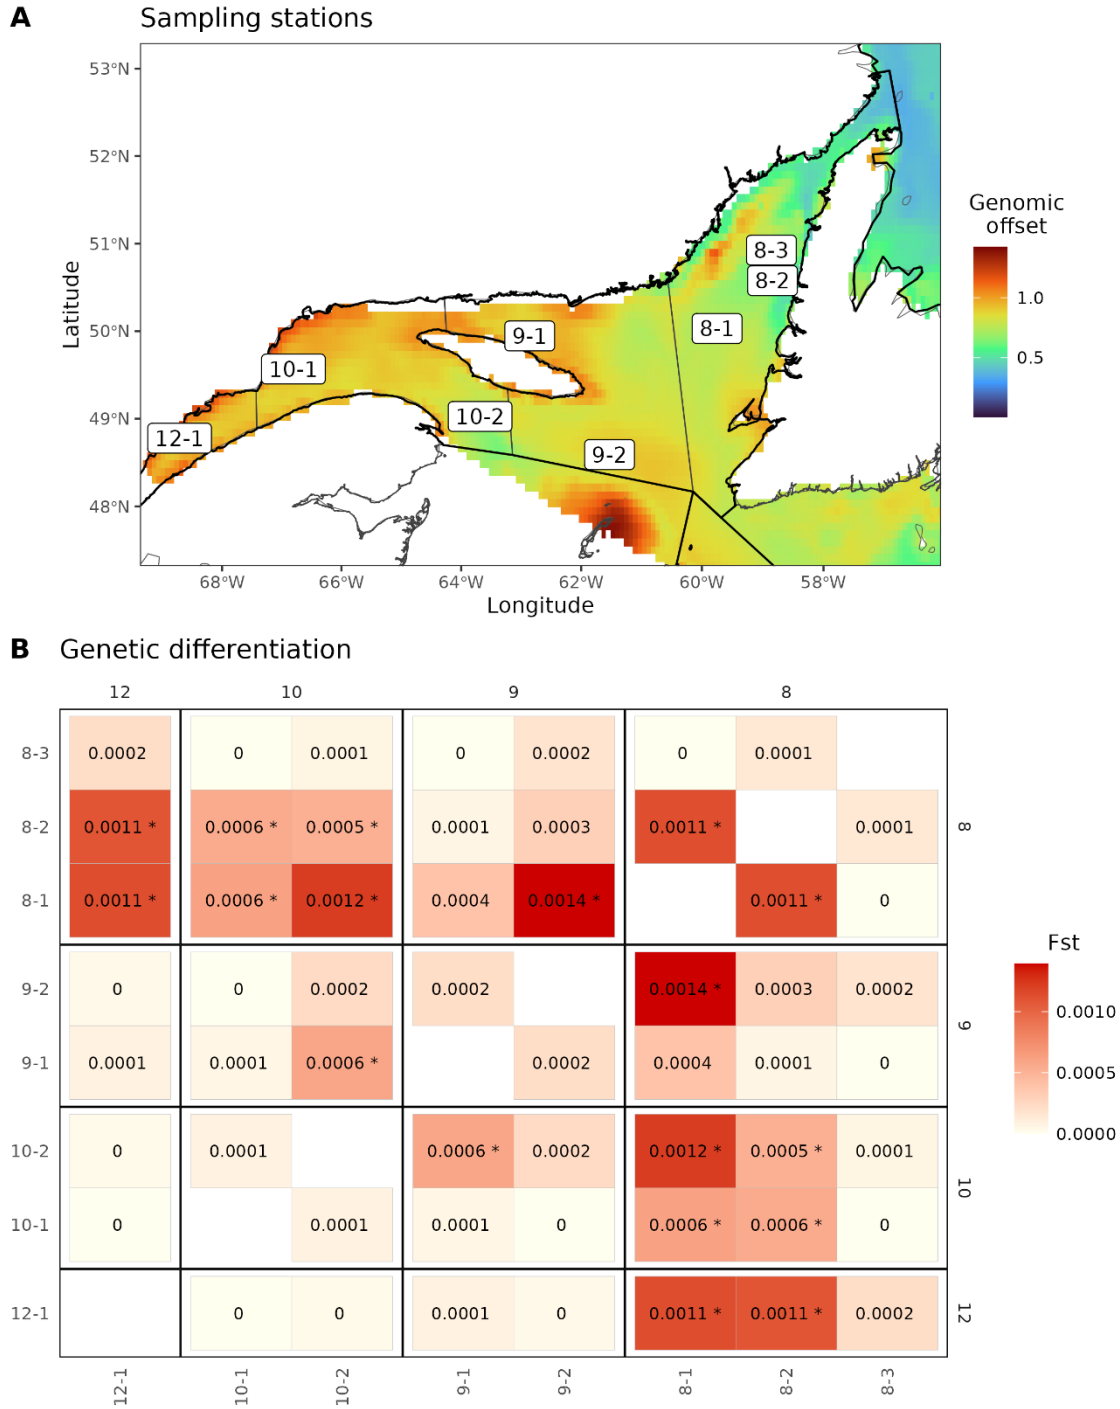

Figure 4. Sampling stations, genomic offset and genetic differentiation in the Estuary and northern Gulf of St. Lawrence. A) Distribution of the eight sampling stations along the predicted genomic offset. The lines show the boundaries separating the current assessment units. B) Measure of genetic differentiation (F_{st}) calculated between all stations. Asterisks (*) indicate F_{st} values significantly different from 0.

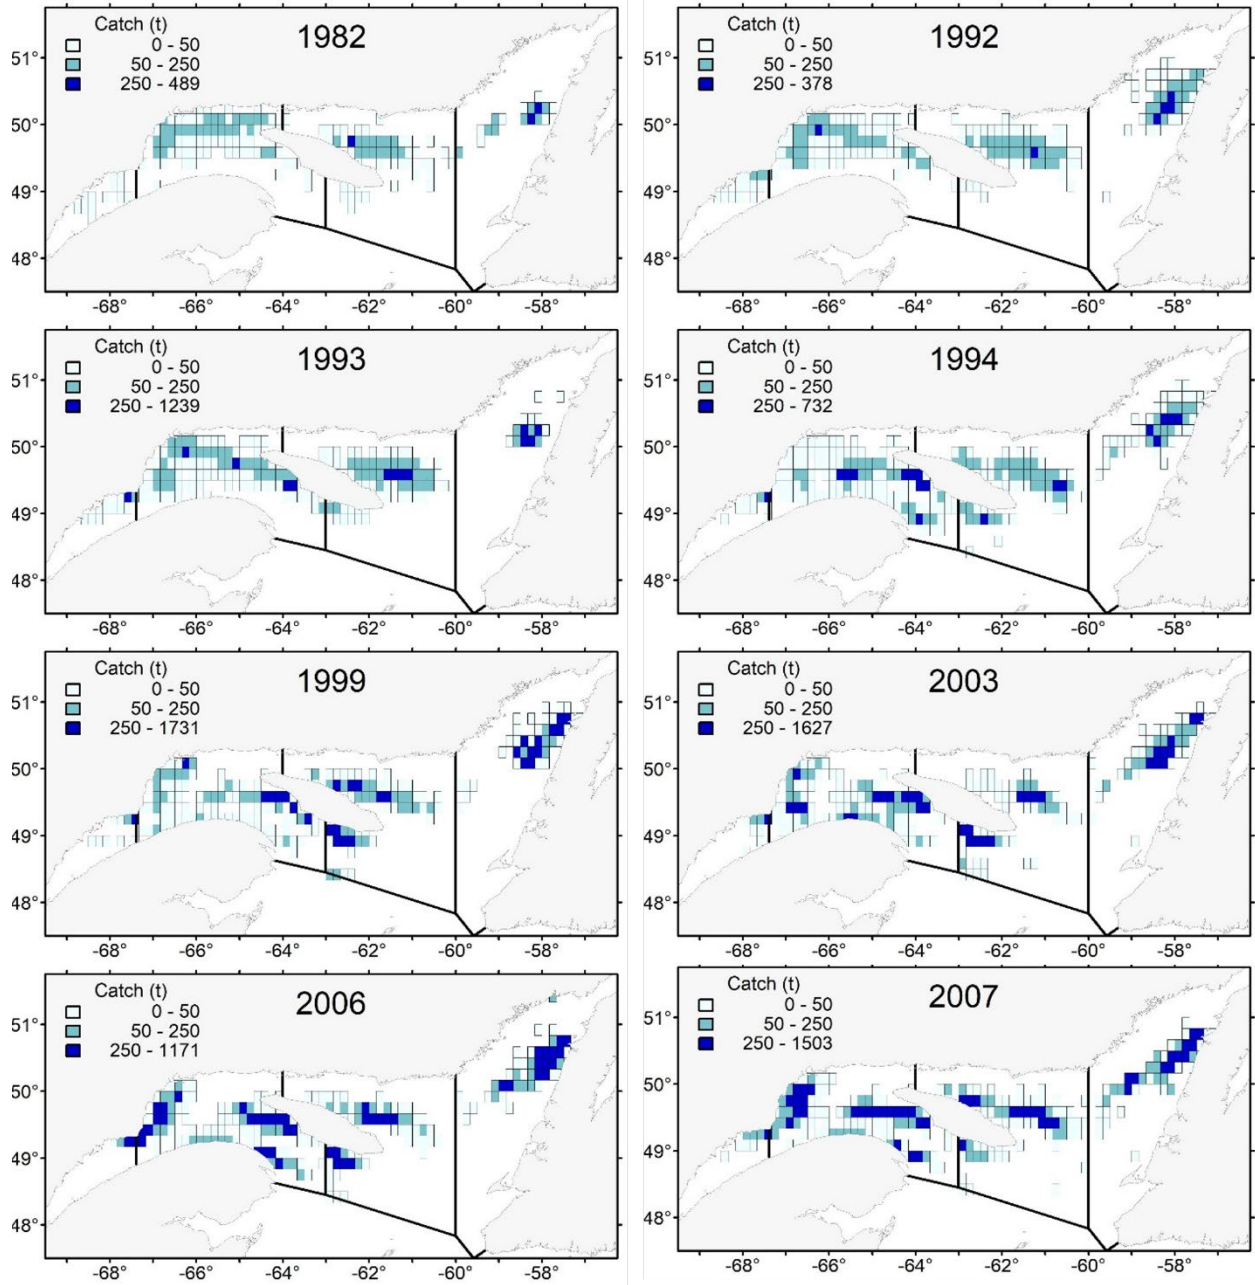

Figure 5. Catch (t) by fishing quadrant in certain years of interest (panels).

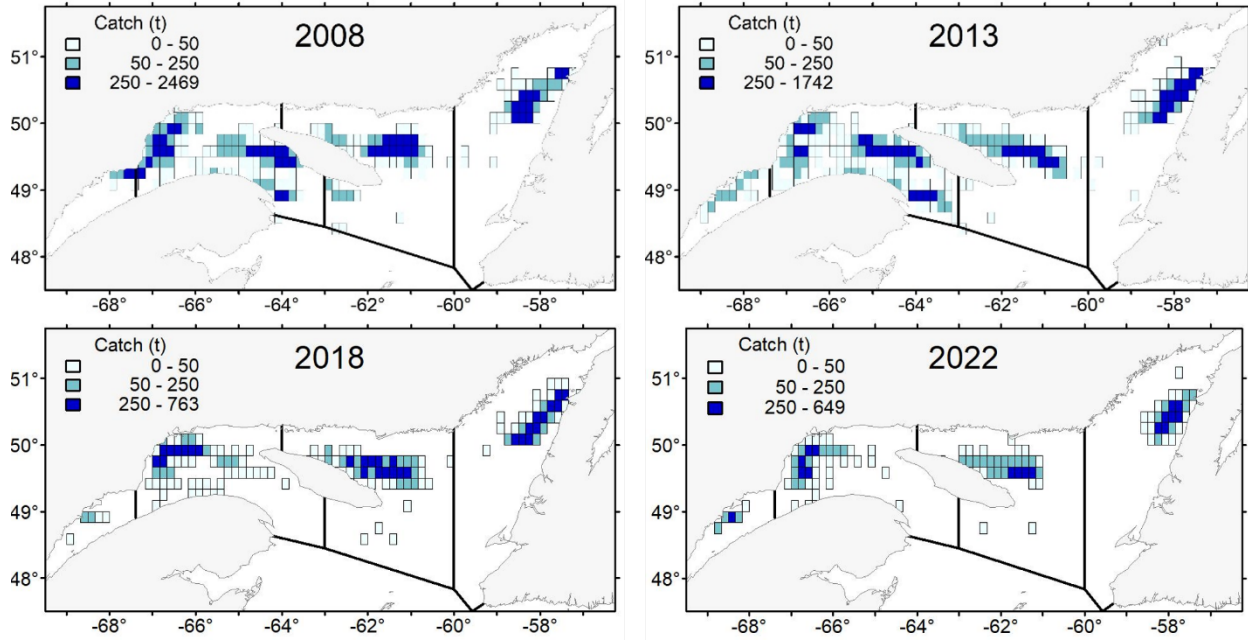

Figure 5. Cont'd.

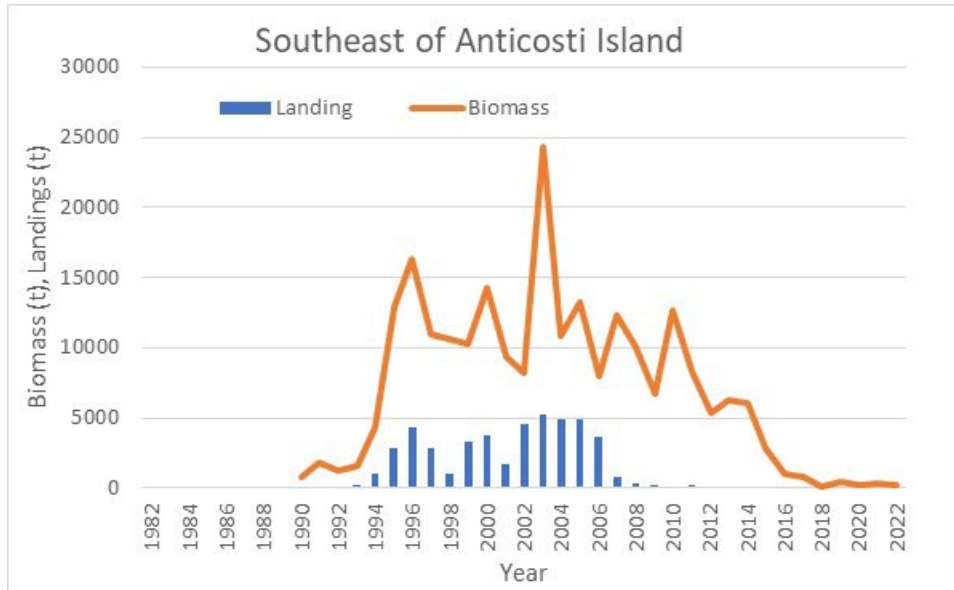

Figure 6. Estimated landings and biomass of northern shrimp in the sector southeast of Anticosti Island which is the sector targeted in the modification of the boundary between the Sept-Iles and Anticosti assessment units.

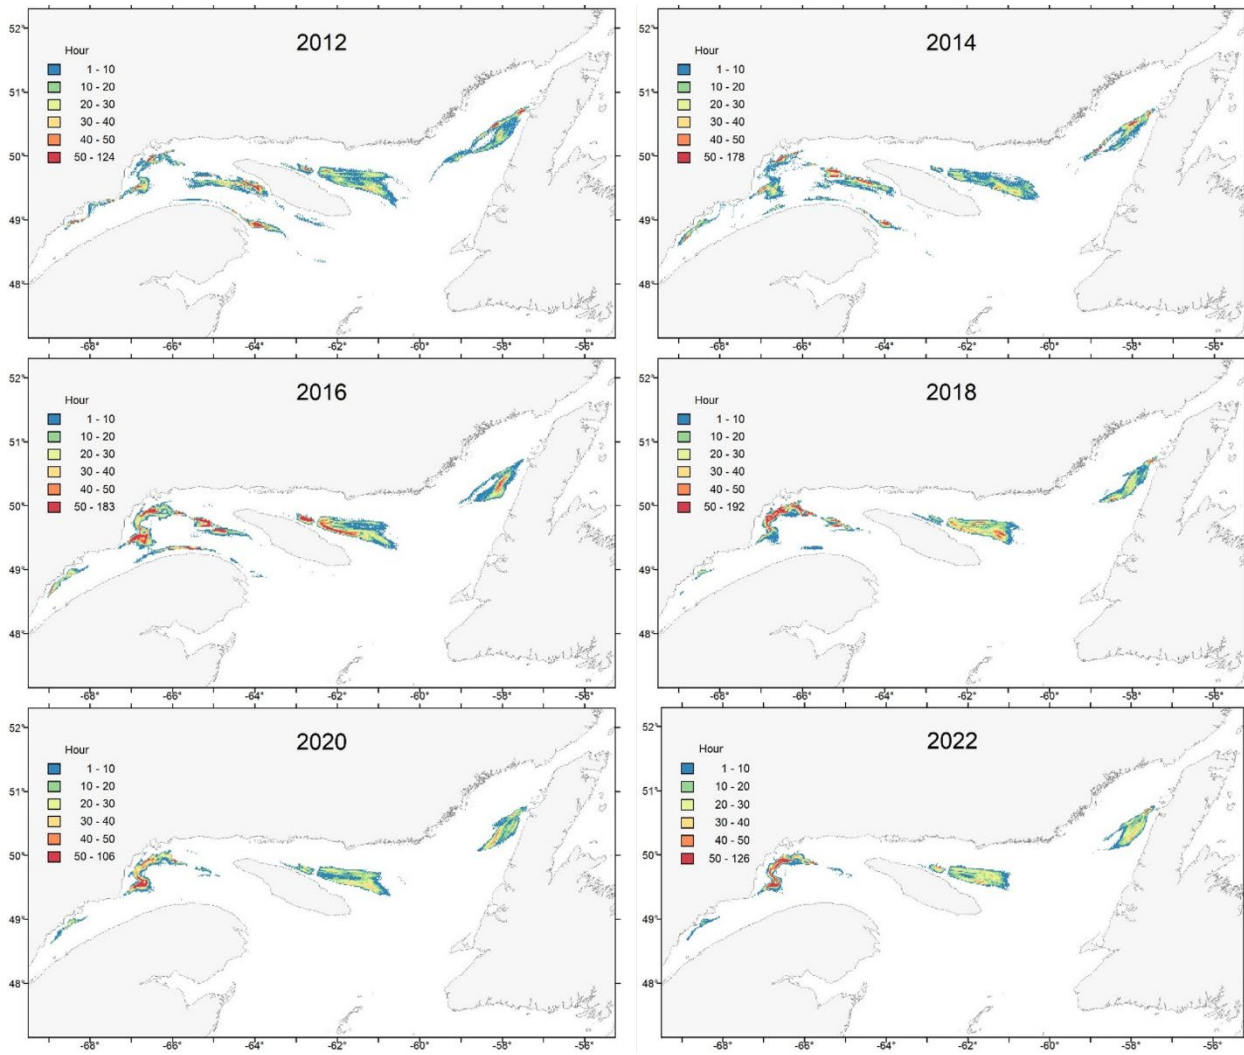

Figure 7. Distribution of fishing effort by shrimpers in the Gulf of St. Lawrence from 2012 to 2022 (only even years are shown) based on Vessel Monitoring System (VMS) data, expressed as the number of hours spent in directed shrimp fishing per 1 minute x 1 minute square.

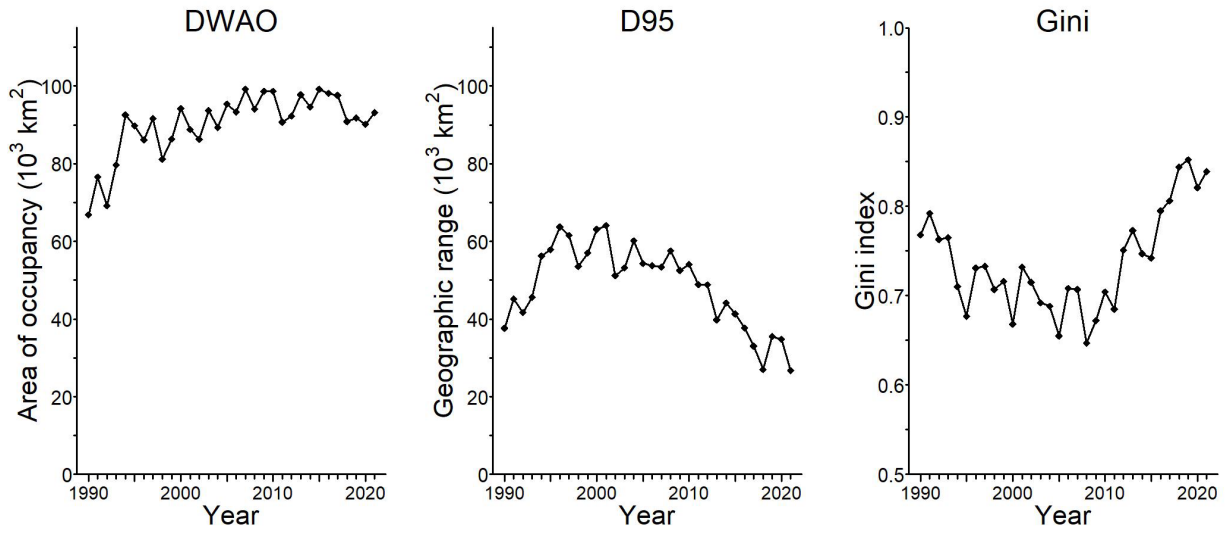

Figure 8. Indices of the spatial distribution of shrimp in the Estuary and Gulf of St. Lawrence: 1) DWAO (design-weighted area of occupancy); 2) D95, or minimum area where 95% of the biomass is distributed; and 3) Gini index. The total study area is 116,115 km².

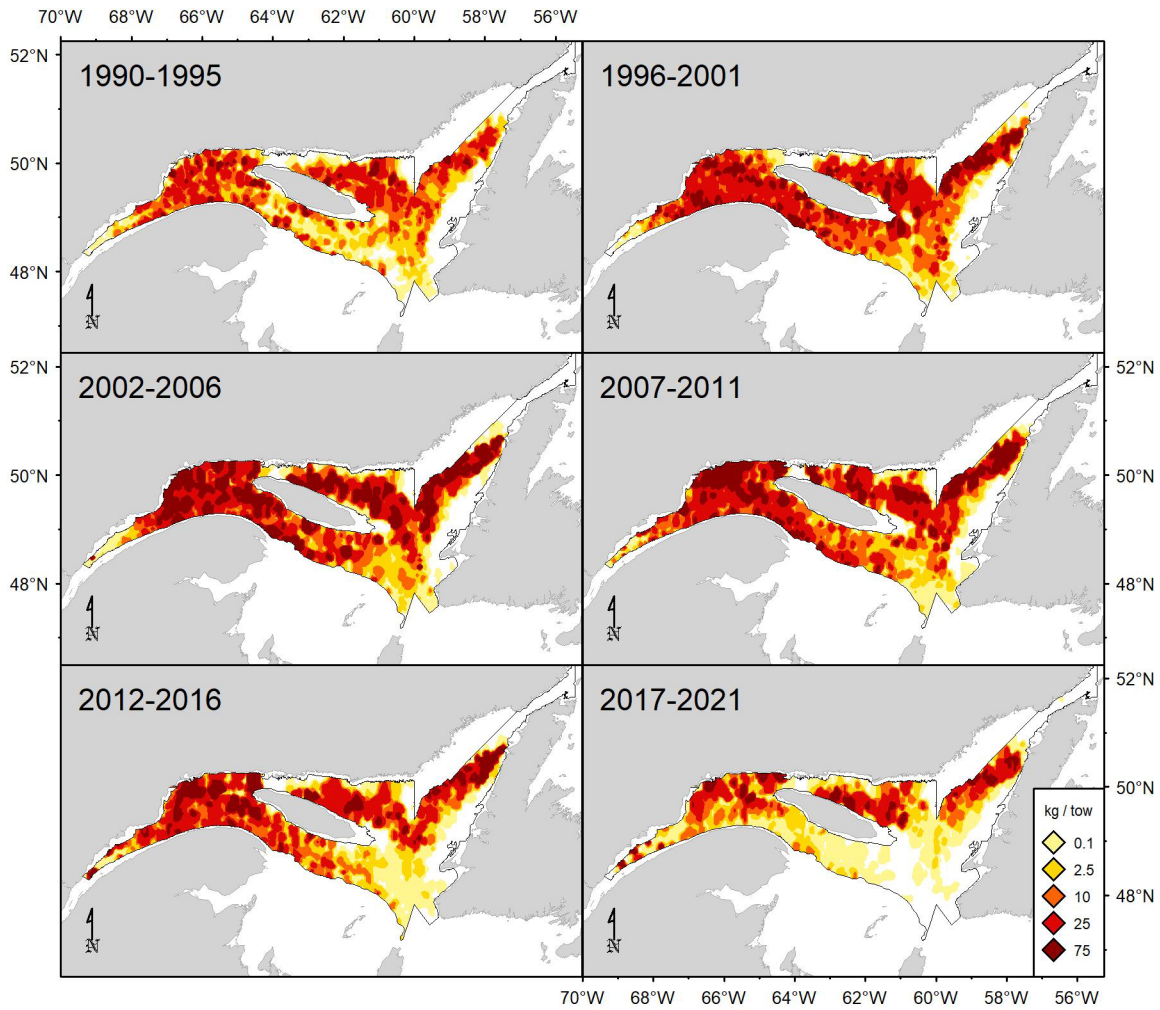

Figure 9. Distribution of northern shrimp catch rates (kg/15 min tow) in the DFO research survey in August.

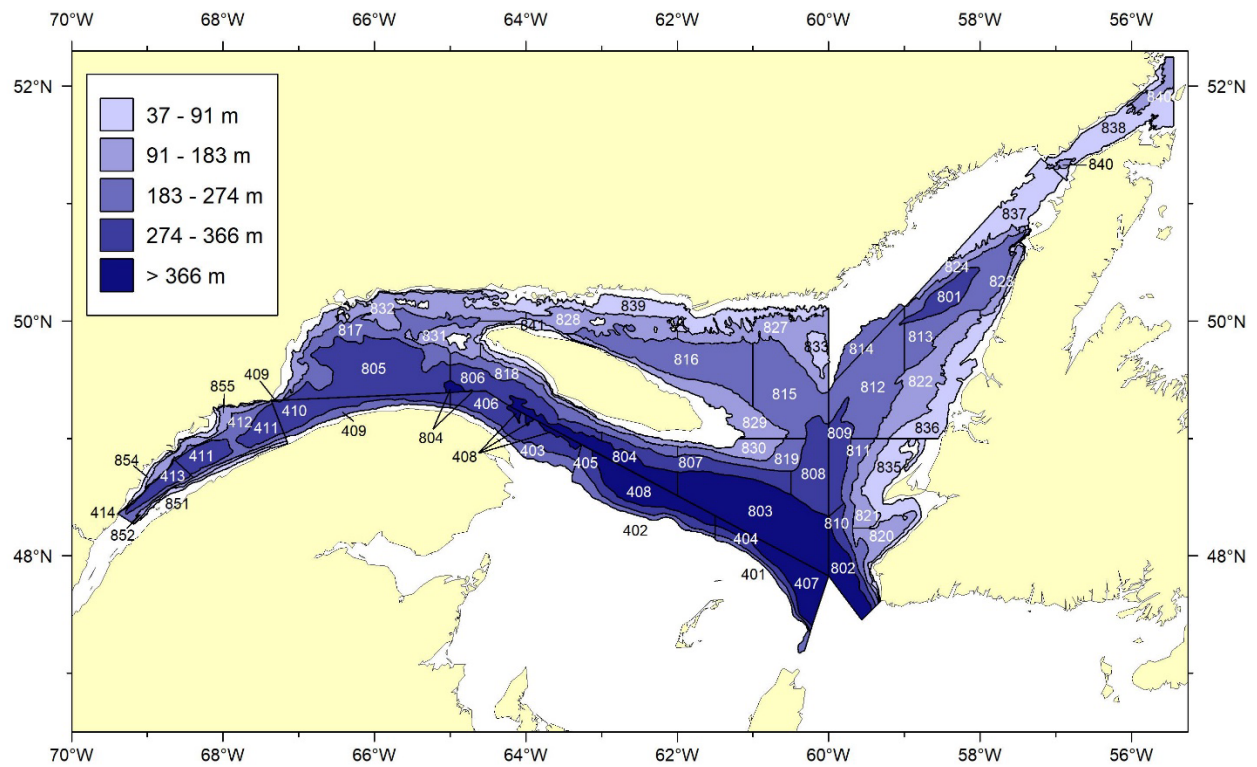

Figure 10. Stratification scheme used in the groundfish and shrimp research survey in the Estuary and northern Gulf of St. Lawrence.

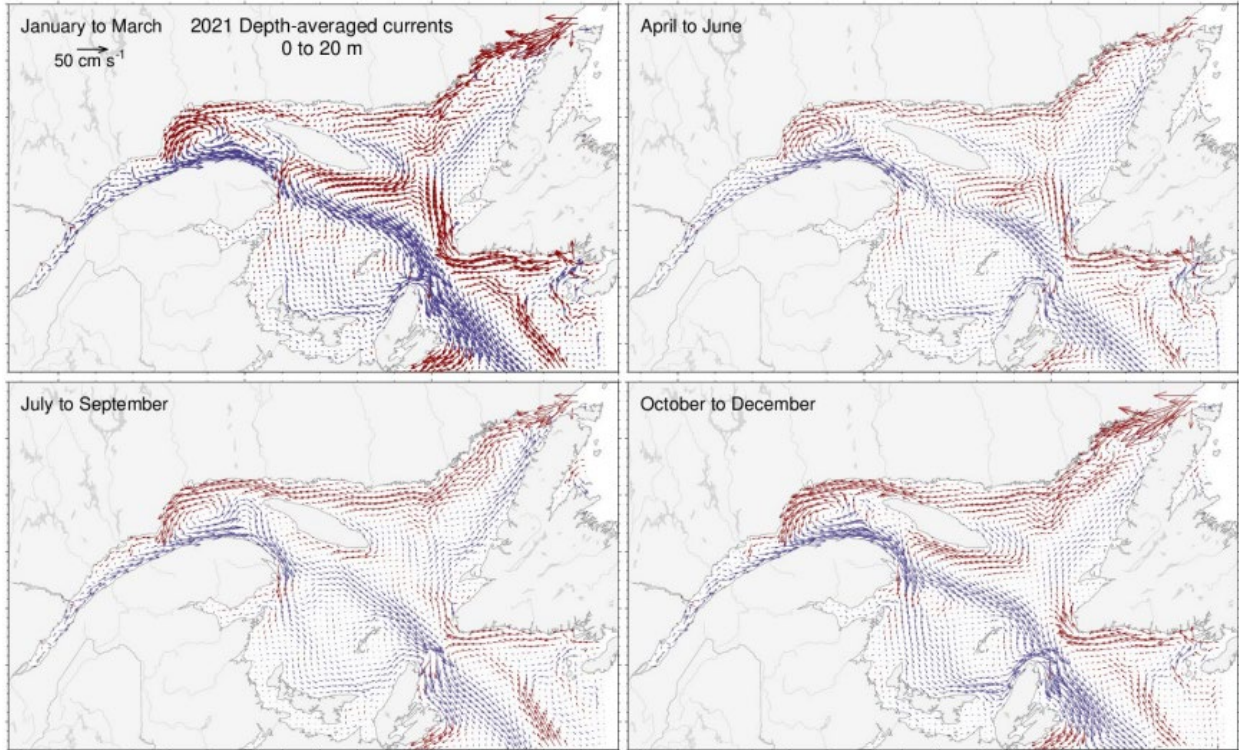

Figure 11. Depth-averaged currents from 0 m to 20 m for each three-month period in 2021. Vectors drawn in blue show eastward movement and those drawn in red, westward movement. Taken from Galbraith et al. 2022.

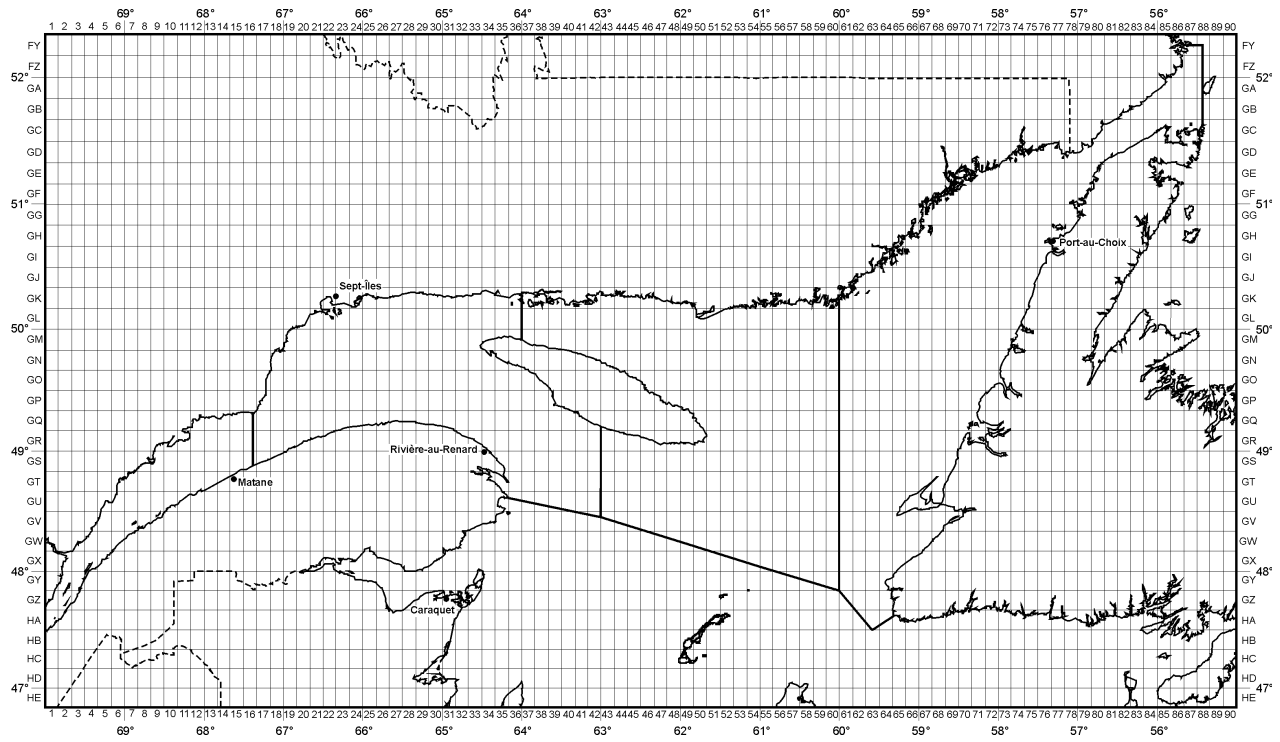

Figure 12. Fishing quadrants (10 minutes longitude x 10 minutes latitude squares) used to map fishing effort spatially in the Canadian Atlantic.

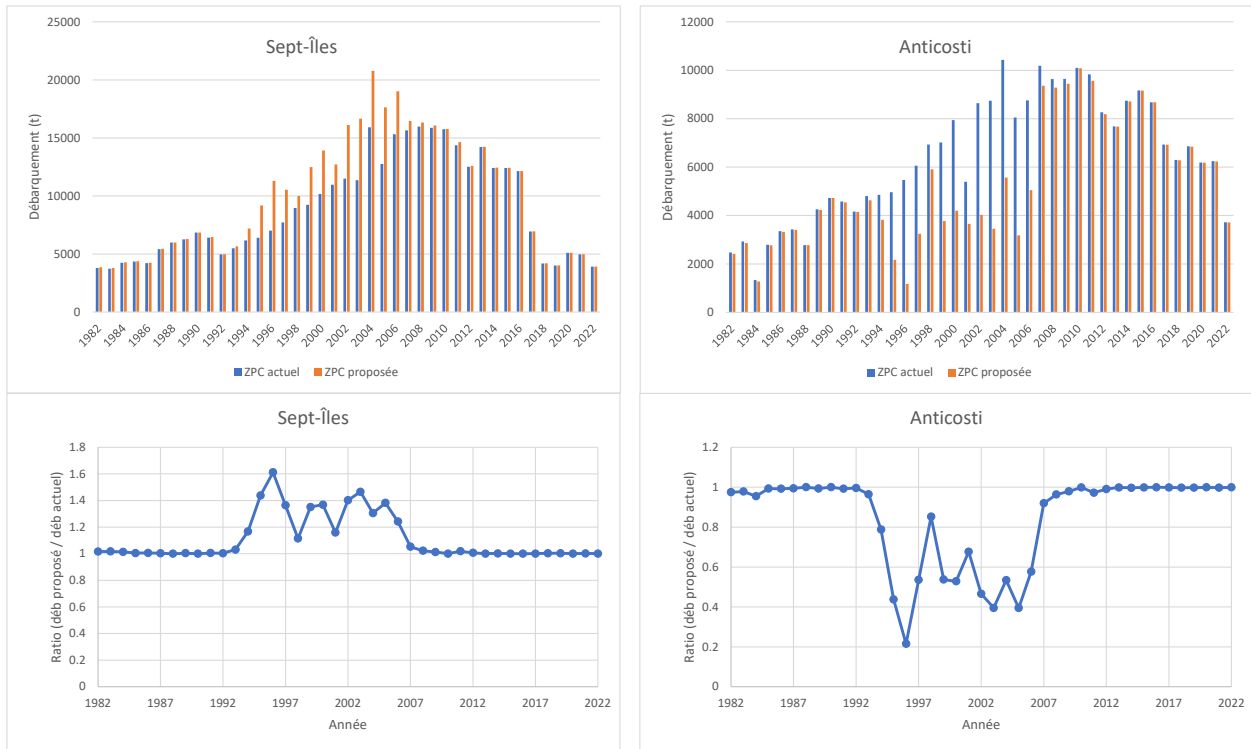

Figure 13. Landings in the Sept-Îles and Anticosti assessment units as defined in the current and proposed delineations (top). The bottom graphs show the ratio between landings in the proposed and current units.

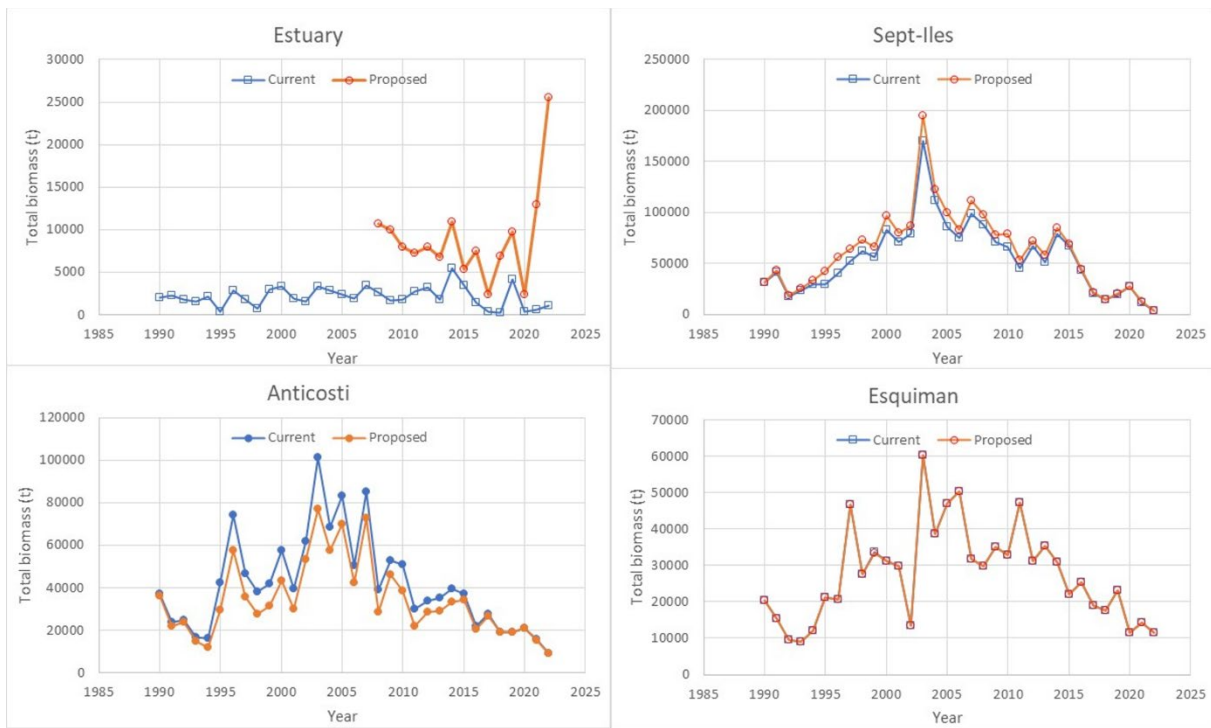

Figure 14. Estimated biomass in the current and proposed assessment units.
