ACKNOWLEDGEMENTS

This project was carried out with financial support from the Geological Survey of Canada, GEM GeoNorth Program, Environmental Geoscience Program - Metal Mining Project, Northern Baselines Activity (2014-2019), Environmental Geoscience Program - Long-term hydrological dynamics of the Mackenzie River Basin Project (2019-2024), Polar Knowledge Canada (Project# 1519-149 to JMG and RTP), Arctic Net (Project #51 to JMG), Natural Sciences and Engineering Research Council of Canada (NSERC; RGPIN 41665-2012 to RTP), the Government of the Northwest Territories via the Cumulative Impact Monitoring Program (Project #151 to MP) and the Northwest Territories Geological Survey (HF), the Tibbitt to Contwoyto Winter Road Joint Venture, Carleton University, and Queen's University, Belfast. We are grateful to Lisa Neville, Andrew Macumber, Shantal Goldsmith, Carley Crann, Fritz Griffith, Thomas Hadlari, Ava Hadlari, and the staff of the Tibbitt to Contwoyto Winter Road, particularly then Director Erik Madsen, for their in-kind contributions and assistance in sample collection. We thank Great Slave Helicopters for air support during the sampling campaign. We thank Lori Campbell for analyzing the mercury content of all samples at GSC-Atlantic. Galloway et al. (2012, 2015, 2018) report sediment particle size and inorganic and organic sediment geochemical data, including Hg measured by ICP-MS from regional lakes, including some of those reported here. Palmer et al. (2015) report surface water chemistry of regional lakes, including some of those reported here. Macumber et al. (2012) report surface water and sediment inorganic geochemistry of the suite of sample lakes from the Tibbitt to Contwoyto Winter Road. Macumber et al. (2018) report and discuss grain size data from the samples collected along the Tibbitt to Contwoyto Winter Road. Sample collection and research was carried out under Aurora Research Institute License numbers: 14435 and 15858. We thank Dr. Manuel Bringué for his internal review.

PROJECT SUMMARY

Total mercury (Hg) concentration was measured in 175 near-surface sediment samples from 169 lakes in the central Northwest Territories. The lakes are located west and southwest of the City of Yellowknife in the Western Interior Platform, near the City of Yellowknife, east and southeast of the City of Yellowknife along the Ingraham Trail (Highway 4), and northeast of the City of Yellowknife along the Tibbitt to Contwoyto Winter Road. Total Hg in the sediment samples ranges from 3 to 317 $\mu\text{g}\cdot\text{kg}^{-1}$. The sediments sampled from lakes in the Western Interior Platform had significantly lower sedimentary Hg concentrations than the other regions.

1. INTRODUCTION

Abundant gold mineralization in the Slave Geological Province of the Northwest Territories (NT), Canada, led to the establishment of numerous mines from the late 1930s to the present day, such as Giant Mine [1948-1999], Con Mine [1938-2003], and Tundra/Salmita [1964-1968 & 1983-1986], and the region remains highly prospective for additional gold development. Historical mineral processing and waste-disposal practices at some mines (Giant, Con, Discovery, and Tundra/Salmita mines) that were employed prior to the development of more efficient technologies and stringent environmental regulations resulted in substantial contamination by arsenic (As), some of which is in a form that is highly toxic, soluble, and bioaccessible (As trioxide, As_2O_3) and

persists in regional lake sediments (Galloway et al., 2018; Schuh et al., 2018; Van Den Berghe et al., 2018).

Regional contamination by As in lake sediments extends more than 30 km from the historic Giant Mine roaster stack (Galloway et al., 2018; Cheney et al., 2020; Jasiak et al., 2021) but is most pronounced within 17.5 km (Palmer et al., 2015), and is focused downwind to the NW (Palmer et al., 2015; Galloway et al., 2018). Contamination is particularly pronounced in Pocket Lake, located on the Giant Mine property, where As concentration in sediments reaches up to 30,000 mg·kg⁻¹ (Thienpont et al., 2016) above a background of 250 mg·kg⁻¹ at 50.25 cm depth (pre-1900 AD) (Thienpont et al., 2016) and <150 mg·kg⁻¹ in strata dated near 1100 cal yr BP (Patterson et al., 2017; Hutchinson et al., 2019; Hamilton et al., 2021). The concentration of As ranges into the 1000s of mg·kg⁻¹ in near-surface sediments of nearby lakes as well (Galloway et al., 2015, 2018). A more detailed description of the history of mining and regional contamination by As is presented in Galloway et al. (2012, 2015, 2018), Jamieson (2014), Palmer et al. (2015), and Sandlos and Keeling (2016). This contamination has been the focus of several subsequent studies on the distribution of As (e.g., Jasiak et al., 2021), impact on aquatic biota (Nasser et al., 2014; Cott et al., 2016; Persaud et al., 2021; Sivarajah et al., 2022) and human health assessments (Cheung et al., 2020).

Although the predominant element of concern associated with gold projects in the region has been As, the concentrations of other elements, such as mercury (Hg) and antimony (Sb), are elevated in environmental media near many of these sites (Houben et al., 2016; Palmer et al., 2019). Mercury amalgamation was used at Giant Mine for gold recovery from 1948 until 1958 (INAC, 2007; Mackenzie Valley Review Board, 2013) and Hg was often released as a by-product of ore roasting and smelting. Few site-specific studies have been done (Thienpont et al., 2016; Pelletier et al., 2021) and little work has been focused on Hg in the regional environment (Houben et al., 2016; Pelletier et al., 2021). Mercury released to the atmosphere can be redeposited through wet/dry deposition in nearby catchment soils and surface waters. However, due to the long (~1 to 1.5 years) atmospheric residence time of gaseous mercury [Hg(0)], Hg deposition in lakes surrounding a point source may not display a local response (Houben et al., 2016). Thienpont et al. (2016) show that Hg levels increased by 2000% to greater than 2.0 µg·g⁻¹ in the upper sediments of Pocket Lake (located on the Giant Mine property), deposited after the late 1950s. In contrast, Houben et al. (2016) in their analysis of 25 lakes within a 25 km radius of the historic Giant Mine roaster stack did not find a correlation with distance and total Hg concentration (range: 0.49 to 2.41 ng/L) in surface waters. However, methylmercury (MeHg) concentrations were higher in lakes closer to the former Giant Mine. Houben et al. (2016) suggest that the high sulfate emissions associated with historical roasting activities may have enhanced rates of Hg methylation in lakes closer to the point source of emission, as increased sulfate concentrations (up to above 50 mg/L) can stimulate sulfate reducing bacteria activity (Gilmour et al., 1992). The greater MeHg concentrations in lakes closest to the historic roaster stack may reflect an indirect response to the increase in sulfate concentration associated with bedrock geology (Yellowknife Bay Formation metavolcanics; Houben et al., 2016) and/or to sulfate emissions from Giant Mine and subsequent deposition into the nearby catchments.

Pelletier et al. (2021) studied lead (Pb) and Hg in six bogs and sediments of five lakes of the Yellowknife region. They report total Hg concentration in lake sediments deposited in pre-

industrial times as ranging between $28 \pm 3 \mu\text{g}\cdot\text{kg}^{-1}$ and $47 \pm 5 \mu\text{g}\cdot\text{kg}^{-1}$, depending on the site, with a mean for all samples of $39 \mu\text{g}\cdot\text{kg}^{-1}$ and a range of 23 to $54 \mu\text{g}\cdot\text{kg}^{-1}$ ($n=116$). Not surprisingly, the total Hg concentration in the pre-industrial lake sediments examined by Pelletier et al. (2021) was greater at sites with more organic matter content, as determined by them using loss-on-ignition. However, this relationship was not significant in their study (when using all samples from all lakes), possibly due to low sample size ($n=5$ sites) (as the authors note) or due to the fact that it is the character, rather than quantity, of organic matter that is most important in terms of sequestering Hg (and other elements; see Galloway et al., 2018) in lake sediments (Kainz and Lucotte, 2006; Haitzer et al., 2002; Sanei et al., 2014; Outridge et al., 2007, 2019). Two of the five lakes sampled by Pelletier et al. (2021) are located in the Taiga Plain ecozone, west of Yellowknife and overlying bedrock of the Western Interior Platform (Figs. 1, 2). Three of their study lakes, and all six bogs studied by them, are located in the Taiga Shield ecoregion that is underlain by components of the Slave Geological Province (Figs. 1, 3). Organic matter appeared to be an important control on Hg accumulation in at least two of the lakes in the Taiga Shield. At one site, lake PL2, Hg concentration increased by only $20 \mu\text{g}\cdot\text{kg}^{-1}$ over the length of the core and remained constant after ~ 1998 . Mercury concentration was strongly related to organic content in this lake. In lake HL1, the trend was similar, but the maximum increase of Hg was $40 \mu\text{g}\cdot\text{kg}^{-1}$, and the relationship to organic matter weaker but still significant. In the sediments of the Taiga Shield lake closest to Yellowknife, lake IGT3-2, a distinct peak in Hg concentration occurred in sediment that accumulated between 1948 and 1981, reaching a maximum of $133 \mu\text{g}\cdot\text{kg}^{-1}$. Following this peak, Hg concentrations declined but remained greater than in pre-industrial sediment. Total Hg concentration was not related to organic matter concentration in this lake. In the lakes located on the Taiga Plain, there was no consistent relationship between sediment organic matter and Hg concentration and Taiga Plains lakes had declining Hg concentration in their sediments after 1975 (lake CL2) and after 1997 (lake HW3-1). In summary, Taiga Plains lakes had lower total Hg concentration in their sediment, and Taiga Shield lakes had higher anthropogenic Hg flux to their sediment (fig. 8, Pelletier et al., 2021; see their paper for methods of anthropogenic Hg flux modelling). These authors conclude that Taiga Shield lakes were slower to recover from a reduction in North American atmospheric emissions of Hg and Pb because accumulation rates of Pb and Hg continued to increase despite decreasing atmospheric deposition in the region. They conclude that as anthropogenic metal accumulation in these lakes was no longer driven by atmospheric emissions, input must be from “external factors affecting catchment contributions”, such as legacy pollution. Geogenic sources of Hg, and other elements involved in the sequestration of Hg (e.g., sulphur) may also be involved in areas underlain by mineralized bedrock. In the pre-industrial peat, Hg concentrations were $42 \pm 15 \mu\text{g}\cdot\text{kg}^{-1}$ ($n=172$, max $96 \mu\text{g}\cdot\text{kg}^{-1}$) (Pelletier et al., 2021). Similar to some of the lake profiles, sub-surface peaks of Hg (to between ~ 140 - $250 \mu\text{g}\cdot\text{kg}^{-1}$) also occurred in peat cores corresponding to peat that accumulated between 1950 and 1980 and these peaks were followed by a return to pre-industrial Hg concentrations in uppermost layers. This body of work indicates that additional research is needed to better understand controls on Hg mobility and fate in the study region. Spatial surveys and additional temporal studies are thus needed.

2. STUDY AREA

The Hay River Lowland of the Taiga Plains Ecozone occurs west and south of Great Slave Lake (Ecosystem Classification Group, 2007). This broad lowland plain is characterized by a subhumid

mid-boreal climate. The mean summer temperature is 13°C and mean winter temperature is -19°C. Mean annual precipitation ranges from 350 to 450 mm. Vegetation is composed of closed mixed stands of trembling aspen (*Populus tremuloides*), balsam poplar (*Populus balsamifera*), white spruce (*Picea glauca*), balsam fir (*Abies balsamea*), and black spruce (*Picea mariana*) on dry or boggy sites. Poorly drained fens and bogs cover 30% of the ecoregion and also support larch (*Larix laricina*).

The Great Slave Lake Plain of the Taiga Plains Ecozone occurs west of the North Arm of Great Slave Lake (Ecosystem Classification Group, 2007). The ecoregion has a low subarctic climate and is underlain by discontinuous permafrost. Mean annual temperature is -6°C with a mean summer temperature of 11.5°C and mean winter temperature of -25°C. Mean annual precipitation ranges between 225 to 300 mm. The ecoregion is dominated by open stands of black spruce and groundcover of Labrador tea (*Ledum decumbens*), ericaceous shrubs, and mosses. Wetlands cover about half of the region.

The Yellowknife study area occurs south of the treeline and lies within the Great Slave Lake Lowland and Great Slave Lake Upland ecoregions of the Taiga Shield Ecozone (Ecosystem Classification Group, 2007). Climate is sub-humid, high-boreal, and characterized by a mean summer temperature of 11°C and a mean winter temperature of -21.5°C. Mean precipitation ranges between 200 and 375 mm. Vegetation is composed of closed stands of trembling aspen, balsam poplar, paper birch (*Betula papyrifera*), and jack pine (*Pinus banksiana*), with white spruce and black spruce dominating later successional stands. Poorly drained fens and bogs are covered with open stands of larch and black spruce. The City of Yellowknife and surrounding area is located in the southwestern Slave Geological Province, District of Mackenzie (Fig. 1). Elevation in the region rises gradually from 157 m above sea level (MASL) near Great Slave Lake to approximately 400 MASL north of 63° latitude. The Yellowknife River is the main drainage for the area. Its southern outlet flows into Yellowknife Bay, Great Slave Lake. Many lakes east of Yellowknife lie within the Cameron River-Prelude Lake watershed. Drainage in the region is influenced by bedrock structure; numerous small elongate lakes have formed along fault and joints in the bedrock.

Northeast of Yellowknife, the Tibbitt to Contwoyto Winter Road (TCWR) traverses the central Slave Geological Province (Fig. 4). The southern end of the TCWR begins in the Tazin Lake Upland Ecoregion of the Taiga Shield Ecozone and travels north into the Coppermine River Upland Ecoregion of the Southern Arctic Ecozone near latitudinal treeline and then into the barrenlands of the Takijuj Lake Upland Region of the Southern Arctic Ecozone near Lac de Gras (Ecosystem Classification Group, 2007). The Coppermine River Upland Ecoregion is characterized by a high subarctic climate with a mean summer temperature of 9 °C and mean winter temperature of -24.5 °C. Annual precipitation ranges from 200 to 300 mm. Vegetation consists of open, stunted stands of black spruce and larch with lesser amounts of white spruce. Shrub or ground cover in these open communities consists of dwarf birch (*Betula glandulosa*), willow (*Salix* spp.), ericaceous shrubs, such as northern Labrador tea and red bearberry (*Arctostaphylos rubra*), cotton grass (*Eriophorum* spp.), and lichen. Poorly drained areas support tussocks of sedge (*Carex* spp.), cotton grass and sphagnum moss (*Sphagnum* spp.). Low shrub tundra consisting of dwarf birch and willow are also common in this ecoregion. Climate of the Takijuj Lake Upland Ecoregion of the Southern Arctic Ecozone is characterized as low arctic, with a mean summer temperature of 6°C and mean winter temperature of -26.5°C (Wiken, 1986).

Annual precipitation ranges from 200 to 300 mm. Vegetation is composed of shrub tundra consisting of dwarf birch, willow, Labrador tea, and ericaceous plants. Low-lying sites support willow, sphagnum moss, and sedge. Scattered stands of spruce may occur along the southern boundary of the ecoregion. Lakes northeast of the City of Yellowknife along the Tibbitt to Contwoyto Winter Road and associated waterbodies drain into four primary drainage basins: the Great Slave Lake and Mackenzie River Drainage Basin, the Coppermine River Drainage Basin, the Back River Drainage Basin, and the Hood and Burnside rivers Drainage Basin. On the southern end, within the Great Slave Lake and Mackenzie River Drainage Basin, the winter road traverses the Cameron, Beaulieu, and Lockhart river watersheds.

2.1 Bedrock and surficial geology

The study area covers two distinct geological districts (Fig. 1). The southern and western portion is underlain by the flat-lying Paleozoic sedimentary successions of the Western Interior Platform while the northern portion of the study area, including the Yellowknife region, rests on Canadian Shield consisting of the Archean to Neo-Proterozoic rocks of the Slave Geological Province.

The bedrock of the Western Interior Platform is composed of Cambro-Ordovician to Devonian quartz-rich and carbonate sandstone, mudstone, dolomite, and limestone (Rhodes et al., 1984). Bedrock of the WIP is overlain by veneers of fine-grained glaciolacustrine sediments associated with Glacial Lake McConnell that formed following deglaciation of the region between 10,000 and 9,600 ¹⁴C yr BP (Smith, 1994; Dyke, 2004). Till deposits range from <1 to 3 m thick to >25 m thick, with thickness increasing locally where karst collapse has created depressions in the bedrock surface. Historic drill hole data show that till can be up to 100 m thick in places (Lemmen, 1990). Till in the area has a silt to fine sand matrix with very little clay (Lemmen, 1998). Till, moraine, and glaciofluvial deposits are extensively reworked into beach deposits composed of bedded sand and gravel (Lemmen, 1998; Gebert, 2008). In other places, fills were washed by wave action that produced a discontinuous coarse lag. Wind action following drainage of the glacial lake formed locally concentrated fine-grained glaciolacustrine sediments into eolian dunes and ridges. Recent deposits in this region include alluvial sediments and organic accumulations in bog and fen settings (Gebert, 2008).

The main bedrock elements of the Slave Geological Province are founded on the granodioritic to tonalitic and related granitoid gneiss of the Central Slave Basement Complex (Bleeker and Davis, 1999) and are composed of the volcanic and turbiditic sedimentary rocks of the Yellowknife Supergroup (Villeneuve et al., 1997). The supracrustal rocks were intruded by several different generations of magma, including syn-volcanic felsic to mafic dykes and sills, three suites of post-Yellowknife Supergroup granites, and Proterozoic intrusions (predominately diabase dykes) (Kjarsgaard et al., 2002). In the Yellowknife study area, the bedrock is dominated by mafic meta-volcanics of the Yellowknife Supergroup (2.71-2.65 Ga; Villeneuve and Relf, 1998) that include basalt, andesite, and pillowed flows that trend north-south and host the major gold deposits. East of Yellowknife, Archean meta-sedimentary rocks predominate and consist of greywacke, slate, schist, and phyllite. Yellowknife Supergroup meta-volcanics and meta-sedimentary rocks are intruded by younger granitoid rocks. West of Yellowknife, granitoid intrusions, consisting of granite, granodiorite, and tonalite, compose the majority of the bedrock. The region is crosscut by several major fault lines, such as the Kam Lake Fault and the West Bay Fault that run through the

city of Yellowknife, separating the volcanic rocks from younger granitoids (Yamashita and Creaser, 1999; Yamashita et al., 1999; Cousens, 2000; Cousens et al., 2002). The region is transected by a variety of un-metamorphosed Proterozoic diabase dykes and over 150 Cretaceous to Eocene kimberlite pipes (Kjarsgaard and Heaman, 1995; Davis and Kjarsgaard, 1997; Kjarsgaard et al., 2002). Numerous greenstone belts (e.g., Courageous Lake greenstone belt) in the Slave Geological Province have resulted in gold exploration and exploitation throughout the region. For detailed description of each component, the reader is referred to Hoffman and Hall (1993), Kjarsgaard et al. (2002), and Helmstaedt et al. (2021). The surficial geology of the Yellowknife region is dominated by a mosaic of Glacial Lake McConnell sediments and glacial tills that infill the topographic lows of the abundant bedrock outcrops. Till is primarily matrix-supported diamicton (Kerr and Wilson, 2000). Clasts consist of various locally derived lithologies and range in size from small pebbles to large boulders. Till in the Yellowknife area may be composed of up to 60% clasts, but most exposures contain approximately 20% to 40% (Kerr and Wilson, 2000). Till exposures have been generally eroded, and are less than 2 m thick, forming discontinuous cover in topographic lows or on bedrock outcrops. Glaciofluvial sediments are relatively uncommon in the study region, and where present consist of fine sand to cobbles in the form of eskers, kames, and outwash (Kerr and Wilson, 2000). A number of surficial sedimentary deposits may be attributed to Glacial Lake McConnell, which infilled Great Slave Lake, Great Bear Lake, and Athabasca Lake basins during deglaciation between 11,800 and 8,300 cal yr BP (Dyke and Prest, 1987; Smith, 1994; Kerr and Wilson, 2000; Wolfe et al., 2014). Sedimentary deposits of Glacial Lake McConnell consist of poorly to moderately sorted coarse to fine sand, silt, and clay that can be up to 20 m thick in some topographic lows (Kerr and Wilson, 2000). These sediments may overlie till, outwash, or bedrock and finer grained sediments deposited in deep water environments and may be overlain by sand and gravel deposited in regressive fluvial or littoral successions. Accumulations of Holocene-aged peat also occur in the study area and can be 1 m thick or greater in bogs and other low-lying wetland types (Kerr and Wilson, 2000).

Further north in the study region, the Lac de Gras area (NTS map sheets 76C and 76D) was covered by the Laurentide Ice Sheet during the last glaciation (Dyke et al., 2002). A transition from southwesterly to northwesterly ice flow occurred during late glacial time (Dredge et al., 1995; Ward et al., 1997). The timing of deglaciation is constrained by a single terrestrial ^{14}C date from plant material contained within an esker of 8500 yr BP, suggesting the landscape was partially deglaciated at this time (Dredge et al., 1995). Sediment cover in this region is mostly composed of a single unstratified till unit. Dredge et al. (1995) and Ward et al. (1997) describe the till as having silty-sandy to sandy matrix and a clast content varying from 5 to 40%. Till can be divided based on surface morphology as well as thickness from till veneer, till blanket, to hummocky till. Till silt content is likely derived from local bedrock sources (granitoids or Yellowknife Supergroup metasediments; Stublely, 2005). Areas of hummocky till have a different geochemical signature to thinner till for some kimberlite pathfinder elements (e.g., Ba, Cr, Mg, Ni; Wilkinson et al., 2001). Variations are attributed to the different bedrock sources of till and transport distances as well as attrition and mixing. Kimberlite indicator minerals such as pyrope, almandine-spessartine garnet, grossular and andradite garnet, diopside, chromite, ilmenite, and olivine are associated with a specific source at transport distances exceeding 70 km (McClenaghan et al., 2002). Modified shaped gold grains with unidentified sources and unknown transport distances are also present (Kerr and Knight, 2007). Potential sources of indicator minerals and till matrix geochemical anomalies include kimberlites, ultramafic dykes, and known volcanogenic massive sulphide

showings as well as a variety of new base, precious, and rare metal showings such as porphyries, alkaline intrusions, and pegmatite. On a landscape scale, stagnant ice associated with the last glaciation created large areas of hummocky till and moraine ridges in the central Slave Geological Province (Kerr et al., 1997). Massive ground ice or icy sediment within till blankets may be present northeast of Contwoyto Lake, evidenced by stabilized thawslides (Wolfe, 2000). Glaciofluvial sediment in the region is commonly contained within tracts of thin or scoured till and exposed bedrock and consists of fine sand to cobbles in the form of eskers, kames, and proglacial outwash (Wolfe, 2000). The tracts, or “corridors” are oriented towards the west or northwest. The relative influence of subglacial scouring, meltwater erosion, and proglacial stagnant water on the origin of these corridors is still debated. Eskers range from small ridges a few tens of metres long to large complexes up to 32 km long and 20-30 m high. Outwash plains with braided channels and kettle lakes are sometimes associated with eskers (Wolfe, 2000). A number of erosional and depositional shoreline landforms associated with a sequence of proglacial lakes that formed in the region surrounding Contwoyto Lake during the last deglaciation are present. These include perched deltas, raised beaches, terraces and spits, wave-cut beaches and washed boulder till surfaces that occur up to 45 m above present lake level (Kerr et al., 1997). Alluvial sediments consisting of gravel and silt-sized sediment deposited by modern streams and rivers are also present (Wolfe, 2000). Accumulations of peat up to 1 m thick are present in topographic lows and poorly drained areas.

Due to the high mineral potential of bedrock in the central Slave Geological Province a large body of literature exists on bedrock geochemistry, but data for Hg is lacking for granitoids, meta-sedimentary, and meta-volcanic rocks in the region (see Table 3 in Galloway et al., 2015). Mercury is documented in early quartz lenses of the Con system (1-0.1 %; along with Pb), in early quartz veins of the Negus-Rycon system (0.1-0.01%), and in quartz-carbonate stringers that cut early quartz lenses of the Campbell system (0.1-0.01%) (values are semi-quantitative spectrographic analyses by the then Spectrographic Laboratory of the Geological Survey of Canada) (table 45, p. 164 in Boyle, 1961). Global values for Hg in continental crust are $0.05 \mu\text{g}\cdot\text{g}^{-1}$ (Rudnick and Gao, 2004 and references therein). Tills in the Yellowknife region can contain As with concentrations up to $1560 \text{ mg}\cdot\text{kg}^{-1}$ within *in situ* weathered material over mineralized zones, but Hg has generally been reported as less than analytical detection limits (Kerr, 2006). The concentration of Hg in glaciofluvial, glaciolacustrine, and peat deposits in the region are either not published or are poorly known due to a lack of regional studies. Pelletier et al. (2021) assessed Hg in six bogs in the Yellowknife region and report Hg concentrations of $42 \pm 15 \mu\text{g}\cdot\text{kg}^{-1}$ ($n=172$, max $96 \mu\text{g}\cdot\text{kg}^{-1}$) in pre-industrial peat samples. Mercury then peaks to between $\sim 140\text{-}250 \mu\text{g}\cdot\text{kg}^{-1}$ in cores corresponding to peat that accumulated between 1950 and 1980 and then returns to pre-industrial concentrations in the uppermost layers of peat.

3. METHODS

3.1 Sampling

One hundred and seventy-seven near-surface sediment samples from 169 lakes were collected during the summer and fall seasons from 2009 to 2014 from either canoes or helicopters. The sediment samples were collected from four main regions: the Western Interior Platform, Yellowknife area, Ingraham Trail, and the Tibbitt to Contwoyto Winter Road (Figures 1, 2, 3, 4;

Table 1). The maximum depth (Z_{max}) of each lake was targeted by sampling near the centre of each lake, but bathymetric data does not exist for most of the studied lakes. For some sites, such as Lake 15 (Great Slave Lake) the maximum depth was not sampled as the site was near shore. Metadata and water quality variables (e.g., dissolved oxygen, temperature, pH) were measured at one metre depth intervals in the water column using a multi-metre probe at the time of collection for most lakes. These results are reported in Galloway et al. (2012) and Macumber et al. (2012). Near-surface sediments were collected using an Ekman grab sampler and were predominantly organic-rich fine-grained material (see Galloway et al., 2012, 2015, 2018 and Macumber et al., 2012, 2018 for additional descriptions of grain size data and organic matter characterization for most of the samples). The top 2 to 5 cm of sediment retrieved in the Ekman grab sampler was sub-sampled for element geochemical analyses and other analyses not reported here. The near-surface sediments (upper 2-5 cm) will undoubtedly represent several decades of sediment accumulation in the low sedimentation sub-arctic lakes sampled. Samples were kept cool in the field and during shipping to Carleton University where they were kept cold at 4 °C prior to geochemical analyses.

Figure 1: Map of the study region.

Lakes were categorized by their geospatial location (Table 1). Lakes underlain by Western Interior Province bedrock were classified as “Western Interior Province” (WIP) lakes (Fig. 2). Lakes underlain by Slave Geological bedrock components east of Behchokò to -114.1574° longitude were classified as “Yellowknife area” lakes (Fig. 3). This area is grouped together because it is the region expected to be impacted by downwind atmospheric deposition from the former Giant Mine (Galloway et al., 2012, 2015, 2018; Palmer et al., 2015; Jasiak et al., 2021). Lakes east of

114.1574° longitude were classified as “east and southeast of Yellowknife along the Ingraham Trail” lakes (Fig. 3). Lakes located along the Tibbitt to Contwoyto Winter Road north of the Ingraham Trail were classified as Tibbitt to Contwoyto Winter Road (TCWR) lakes (Fig. 4).

Figure 2: Map of the study lakes in the Western Interior Platform region. Location of lakes CL2 and HW3-1 studied by Pelletier et al. (2021) shown by blue symbol.

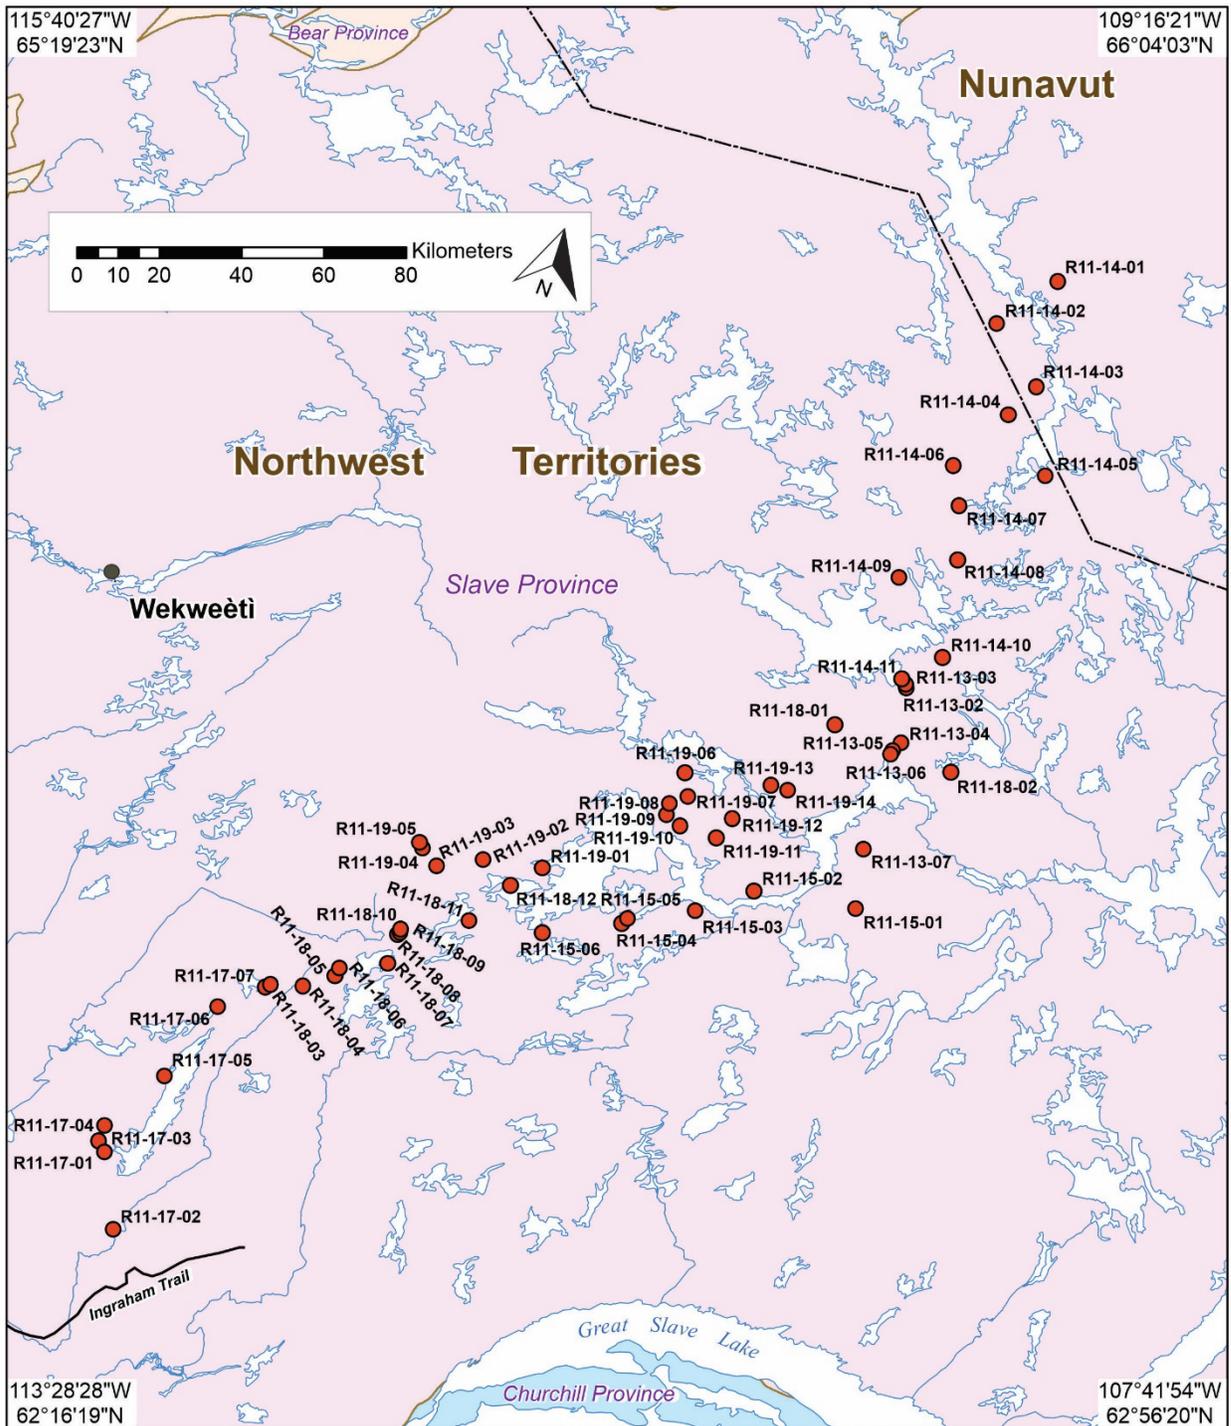

Figure 4: Map of the study lakes along the Tibbitt to Contwoyto Winter Road.

3.2 Mercury analysis

Mercury data derived from ICP-MS for the lakes herein studied are reported in Galloway et al. (2015). In this report, we present total Hg measured using thermal decomposition followed by amalgamation and atomic absorption spectrometry in the near-surface sediments of 169 lakes in the Yellowknife area and surrounding regions. Mercury analysis using thermal decomposition followed by atomic absorption spectrometry generally offers better detection limits than ICP-MS analysis, reduces the likelihood of contamination or Hg loss through volatilization during traditional digestion, is a sensitive method, and is appropriate for small sample sizes (Hall and Pelchat, 1997; Leiva et al., 2013).

Total Hg concentration was determined on freeze-dried sub-samples (average mass 68 mg) by the Geological Survey of Canada in Dartmouth, Nova Scotia, using a Leco AMA-254 Direct Mercury Analyzer. Samples were thermally decomposed at 750°C, followed by collection of the Hg vapour on a gold amalgamator and measurement by atomic absorption spectrophotometry. Replicate samples ($n=10$) were analyzed to assess analytical precision. Mean Relative Percent Difference (RPD) is 4.6 ± 4.4 SD $\mu\text{g}\cdot\text{kg}^{-1}$. One sediment certified reference material from the National Research Council of Canada (MESS-3, $n=9$) was used to assess analytical accuracy. For MESS-3, mean measured Hg concentration is 94.4 ± 1.8 $\mu\text{g}\cdot\text{kg}^{-1}$ ($n=9$) versus a certified concentration of 91 ± 9 $\mu\text{g}\cdot\text{kg}^{-1}$. The standard HISS-1 was also used ($n=9$), that has mean measured Hg concentration is 5.5 ± 0.4 SD $\mu\text{g}\cdot\text{kg}^{-1}$ ($n=9$) versus a provisional concentration of 10 $\mu\text{g}\cdot\text{kg}^{-1}$ that has been routinely measured as being 5-6 $\mu\text{g}\cdot\text{kg}^{-1}$ in GSC laboratories. Elemental analyses, organic geochemistry (sequential pyrolysis), and sedimentary grain size for most of the samples reported here are reported in Galloway et al. (2012, 2015, and 2018) and Macumber et al. (2012, 2018). Surface water chemistry of the lakes along the TCWR are reported in Macumber et al. (2012) and for the Yellowknife region in Palmer et al. (2015).

Statistical analyses of total Hg data in lake sediments were conducted using JASP 0.16.4 (JASP, 2022) to determine if total Hg concentration in the near-surface sediment samples varied by region. A Levene's test for equality of variance showed that the data did not meet the assumption of homogeneity of variance ($F=5.948$, $p<0.001$) needed for use of the parametric ANOVA test. A non-parametric alternative was thus needed and the Kruskal-Wallis test with Dunn's post-hoc comparisons was used (Dunn, 1961).

RESULTS AND DISCUSSION

Of the 177 samples analyzed, two samples (LK0601, LK0603) had insufficient material for Hg analysis. Three samples (LK19S1, R11-15-002, R11-14-01) had Hg concentrations below detection (5 $\mu\text{g}\cdot\text{kg}^{-1}$); a value of half the method detection limit was used (2.5 $\mu\text{g}\cdot\text{kg}^{-1}$) for statistical analyses. Mercury concentrations ranged from 3 to 317 $\mu\text{g}\cdot\text{kg}^{-1}$ with a median of 68 $\mu\text{g}\cdot\text{kg}^{-1}$ ($n=175$) (Table 1).

Table 1: Total Hg concentration measured in near-surface lake sediment samples, replicates, and certified reference material MESS-3 and the internal standard HISS-1.

C-number = GSC Curation number; INS = insufficient material for analyses; WIP = Western Interior Platform; YK area = Yellowknife area; E and SE along IT = east and southeast of Yellowknife along Ingraham Trail; TCWR = Tibbitt to Contwoyto Winter Road (see Figs. 2, 3, and 4 for map of study lakes for each region).

The total Hg concentrations include some values that are above the Canadian Council Ministers of Environment Interim Sediment Quality Guideline for Freshwater of $170 \mu\text{g}\cdot\text{kg}^{-1}$ (CCME, 1999). This guideline was exceeded in 18 (10%) of samples. The only areas where sedimentary Hg concentration in near-surface sediments did not exceed the ISQG level for Hg were those in the Western Interior Province and east and southeast of Yellowknife along the Ingraham Trail (Tables 1, 2; Fig. 5). The concentration of Hg in all samples is below the Probable Effect Level of $486 \mu\text{g}\cdot\text{kg}^{-1}$ (CCME, 1999).

Table 2: Total Hg concentration (median min, max, $\mu\text{g}\cdot\text{kg}^{-1}$) in near-surface sediments of lakes sampled in different geospatial regions. See Figs. 2, 3, and 4 for location of lakes in each region.

Region	Western Interior Platform	Yellowknife area	East and southeast of Yellowknife along the Ingraham Trail	Tibbitt to Contwoyto Winter Road
Median (min-max)	32 (7-102)	75 (3-249)	62 (11-160)	76 (3-317)
<i>n</i>	29	49	40	57

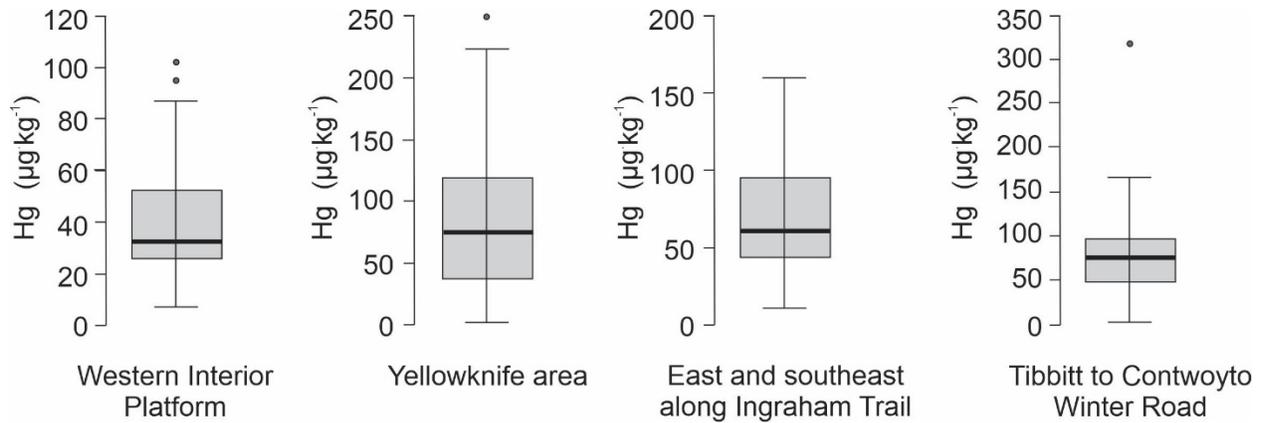

Figure 5: Box-Whisker plots showing minimum value, second quartile, median, third quartile, and maximum value of total Hg concentration in near-surface lake sediments by region (Table 1; Figs. 2, 3, 4). Note differences in scale.

A Kruskal-Wallis test ($H=15.689$, $p=0.001$, $df=3$) shows that the total Hg concentration varies significantly by geospatial location. The pairwise comparison using Dunn's test indicates that sedimentary Hg concentration was significantly lower in sediments of lakes from located in the Western Interior Platform region compared to the other geospatial categories (Table 3). No other differences were statistically significant at the $p<0.05$ level.

Table 3: Dunn's post hoc comparison of total Hg concentration in sediments of lakes categorized by location. *P*-values <0.05 are in bold italics. P_{bonf} = Bonferroni adjustment; P_{holm} = Holm's Bonferroni correction.

Comparison	<i>z</i>	W_i	W_j	<i>p</i>	P_{bonf}	P_{holm}
YK area vs. E and SE along IT	0.616	96.541	89.888	0.538	1	1
YK area vs. TCWR	0.017	96.541	96.377	0.987	1	1
YK area vs. WIP	3.542	96.541	54.5	<i><0.001</i>	<i>0.002</i>	<i>0.002</i>
E and SE along IT vs. TCWR	-0.621	89.888	96.377	0.535	1	1
E and SE along IT vs. WIP	2.864	89.888	54.5	<i>0.004</i>	<i>0.025</i>	<i>0.017</i>
TCWR vs. WIP	3.624	96.377	54.5	<i><0.001</i>	<i>0.002</i>	<i>0.002</i>

WIP = Western Interior Platform; YK area = Yellowknife area; E and SE along IT = east and southeast of Yellowknife along Ingraham Trail; TCWR = Tibbitt to Contwoyto Winter Road

The median total Hg concentration in near-surface sediments in lakes from the Yellowknife area, east and southeast of Yellowknife along the Ingraham Trail, and along the Tibbitt to Contwoyto

Winter road are significantly higher than in sediments of lakes in the Western Interior Platform (Tables 2, 3; Fig. 5). This result suggests that at least some of the accumulated Hg in lakes underlain by Slave Geological Province rocks is associated with the bedrock geology and derived surficial materials. Houben et al. (2016) suggested a potential source of Hg to surface waters in their study of 25 lakes within a 25 km radius of the historic Giant Mine related to the Yellowknife Bay Formation that may have been a source of both Hg and sulfate, and that the sulfate promoted the methylation of the Hg (from geogenic and/or anthropogenic sources) in surface waters. However, Pelletier et al. (2021) report comparable sedimentary Hg concentration in sediments of two lakes from the Taiga Plains and three from the Taiga Shield. Pelletier et al. (2021) report total Hg concentration in lake sediments deposited in pre-industrial times in five lakes in the Taiga Plains and Taiga Shield ecoregions as ranging between $28 \pm 3 \mu\text{g}\cdot\text{kg}^{-1}$ and $47 \pm 5 \mu\text{g}\cdot\text{kg}^{-1}$. Three of the lakes are located on Taiga Shield (Lake PL2, HL1, IGT3-2) (Fig. 3). In the sediment of those lakes, Hg deposited in pre-industrial times (pre-1940) ranged from 32 to 35 $\mu\text{g}\cdot\text{kg}^{-1}$ (lake PL2), from 23 to 54 $\mu\text{g}\cdot\text{kg}^{-1}$ (lake HL1), and from 43 to 75 $\mu\text{g}\cdot\text{kg}^{-1}$ (lake IGT3-2). In sediments deposited after 1940, Hg ranged from 35 to 48 $\mu\text{g}\cdot\text{kg}^{-1}$ (lake PL2), 33 to 72 $\mu\text{g}\cdot\text{kg}^{-1}$ (lake HL1), and 62 to 133 $\mu\text{g}\cdot\text{kg}^{-1}$ (lake IGT3-2) (Pelletier et al., 2021). In the two lakes located in the Taiga Plains (Fig. 2), sedimentary Hg concentrations ranged from 32-85 $\mu\text{g}\cdot\text{kg}^{-1}$ in pre-1940 sediment and from 30-56 $\mu\text{g}\cdot\text{kg}^{-1}$ in post-1940 sediment in lake HW3-1 and from 34-56 $\mu\text{g}\cdot\text{kg}^{-1}$ in pre-1940 sediment and from 22-66 $\mu\text{g}\cdot\text{kg}^{-1}$ in post-1940 sediment in lake CL2.

The lake sediment Hg concentrations reported by Pelletier et al. (2021) are comparable to the median Hg concentration in near-surface lake sediments of the Yellowknife area (75 $\mu\text{g}\cdot\text{kg}^{-1}$), east and southeast of Yellowknife along the Ingraham Trail area (62 $\mu\text{g}\cdot\text{kg}^{-1}$), along the Tibbitt to Contwoyto Winter Road (76 $\mu\text{g}\cdot\text{kg}^{-1}$), and of the Western Interior Platform area (32 $\mu\text{g}\cdot\text{kg}^{-1}$), but the range in sedimentary Hg values reported here are greater (Table 2) (Western Interior Platform 7-102 $\mu\text{g}\cdot\text{kg}^{-1}$; Yellowknife area 3-249 $\mu\text{g}\cdot\text{kg}^{-1}$, east and southeast along Ingraham Trail 11-160 $\mu\text{g}\cdot\text{kg}^{-1}$; Tibbitt to Contwoyto Winter Road 3-317 $\mu\text{g}\cdot\text{kg}^{-1}$), reflecting the larger sample size and variations in organic matter, as well as possibly grain size, mineral input, catchment and lake area, and climate.

CONCLUSIONS

Total Hg concentration ranged from 3 to 317 $\mu\text{g}\cdot\text{kg}^{-1}$ in 175 near-surface sediments collected from 169 lakes in the central Northwest Territories. Total sedimentary Hg concentration is significantly lower (median 32 $\mu\text{g}\cdot\text{kg}^{-1}$, range 7-102 $\mu\text{g}\cdot\text{kg}^{-1}$) in lakes underlain by Western Interior Platform bedrock than in lakes underlain by Slave Geological Province bedrock. Future work is needed to focus on the mobility and fate of Hg in high northern latitude environments.
